FRONT

Preface

This Ph.D. thesis summarizes my scientific research in collaboration with the Niels Bohr Institute (NBI) and the Globe Institute, University of Copenhagen, and was funded by the Lundbeck Foundation. The research was supervised by Associate Professor Troels C. Petersen (NBI) and Assistant Professor Thorfinn S. Korneliussen (Globe Institute).

Being a multi-disciplinary project, the research presented in this thesis is multi-faceted and covers a wide range of topics with the main scope being the development and integration of a novel statistical methods and machine learning models for the analysis of large-scale biological data. The thesis is organized as follows. First I present a brief introduction to the statistical methods and machine learning models used in the thesis. Then I present the research in the form of four papers, each of which reflects a different aspect of the research.

The first paper presents a novel method I developed for detecting and classifying ancient DNA damage in metagenomic samples taking the full taxonomic information into account. While the first paper focuses on the development of the statistical model in the field of ancient genomics, the second paper focuses on the use of modern machine learning models in medicine and how advanced boosted decision trees can not only improve the accuracy of identifying patients at risk of being readmitted after knee or hip surgery, but doing so in a way that is interpretable as well.

In the beginning of 2020 we all experienced how COVID-19 suddenly changed our lives and impacted our societies in dramatic ways. During this time, I ended up working for Statens Serum Institut, the Danish CDC, on a project to develop an agent based model capable of simulating the spread of COVID-19 in Denmark. This model is presented in the third paper and was used to inform the Danish government on how to best handle the pandemic in the early stages and the effect of contact tracing.

Finally, in the fourth paper I show how advanced Bayesian methods can be utilized to better estimate the diffusion coefficients of molecules in the cell nucleus in XXX experiments.

Acknowledgements

First of all I want to express my sincere gratitude to my long time supervisor, captain, and friend: Troels. You are truly an inspiration to work with. I want to thank you for opening so many doors for me, both academically, professionally, and nautically. I am looking forward to our future adventures together. I also want to thank my co-supervisor, Thorfinn. I want to thank you for introducing me to the field of bioinformatic and helping me to develop my skills in this area. I also want to thank you for your patience and guiding me through the endless amount of (near) identical biological concepts and helping me to understand the minute differences.

I have been fortunate to work with people from a wide range of backgrounds and disciplines during my Ph.D. The author lists on the papers in this thesis include a particle physicist, bioinformaticians, a clinical professor, epidemiologists, a medical doctor, a bio-physicist, a mathematician, a biologist, and the president of the Royal Danish Academy of sciences and letters. Before anything else, I want to thank all of my co-authors for their work and contributions to these papers and for allowing me to be a part of their projects. I have learned a lot from all of you, and I hope that I have been able to contribute something to your work as well.

I am thankful for all the people who have helped me with my work and listened to my complaints when I was stuck, when the code did not compile, or when the small bug was almost impossible to find (which was not a small amount of time). In particular I want to thank the people at Globe who I have spent the most time with; Rasa, Alba, and Rasmus. I also want to thank the Korneliussen Group and the people in my office for helpful advice, suggestions and discussions. This also includes Daniel Nielsen and Rasmus Ørsøe from NBI. Finally, I want to thank Mathias Heltberg for many years of fruitful collaboration and for including me in his projects.

This project would not have been possible had it not been for the Lundbeck Foundation which funded my Ph.D. In addition to the funding itself, I am grateful for the inter-disciplinary aspect of project which has allowed me to meet so many inspiring and talented people and for the freedom to pursue my own interests within the project.

I would also like to express my gratitude to Professor Guido Sanguinetti from the International School for Advanced Studies, SISSA, in Trieste, Italy, for hosting me in his group during the Winter of 2021/2022. My gratitude also goes out to Kosio, Sara, Max, Romina, Noor, Viplove, Anne-Marie, and all the other wonderful people that I met during in Trieste. Thanks for making my stay in Italy so enjoyable and for welcoming me in a way that only non-Danes can do.

I want to thank my friends for always being there for me. A special thanks to my friends from NBI and Borchen who I know that I can always count on, whether or not that includes a trip in the party bus of the Sea, taking Artemis out for a sail, or board games and beer. Thank you for always being there. I also want to thank my family, especially my parents for their unconditional support and encouragement. I am grateful for the opportunities that they have given me and for the sacrifices that they have made for me.

Lastly, I want to thank my future wife and mother of our child, Anna. I would not have been able to do this without you. Thank you for your patience and support. I am looking forward to our future together. I love you to the moon and back.

Abstract

Basically a thesis (book?) class for Tufte lovers like myself. I am aware that `tufte-latex` already exists but I just wanted to create my own thing.

Dansk Abstract

Her et dansk abstract.

Publications

MAIN

1 *Introduction*

This class is my personal mix of different book design influences: mainly the works of Edward R. Tufte, (Heltberg et al., 2022; Korneliussen, Albrechtsen, and Nielsen, 2014) known for the big margin and the plentiness of sidenotes and sidecaptions. The margins are however not as prominent as in Tufte's works, the main text takes a bit more space, more like in Robert Bringhurst's typographer's bible (Heltberg et al., 2022).

So it is a bit of a mix of Tufte and Bringhurst, with some of my own choices for other design features, as we will see through this chapter.

1.1 *Bayesian Statistics and Ancient DNA*

While `tufte-style-thesis` is a class for typesetting theses, the general layout is pretty much the same as in a regular book. A book is traditionally divided into three major sections: the front matter, the main matter and the back matter.

Abstract

¹⁰ **1. Motivation** Under favourable conditions DNA molecules can survive for more than two million years (Kjaer et al in press). Such genetic remains can give unique insights to past assemblages, populations and evolution of species. However, DNA is degraded over time, and are therefore found in ultra low concentrations making it highly prone to contamination from modern DNA sources. Despite strict precautions implemented in the field (Llamas et al., 2017), DNA from modern sources does appear in the final output data. ¹⁴ One authenticity criteria used in all ancient DNA studies are the high nucleotide mis-incorporation rates that can be observed as a result of chemical post-mortem DNA damage, in fact misincorporation patterns have become instrumental to authenticate ancient sequences. To date this has primarily been possible for single organisms (Jónsson et al., 2013) and recently for assemblies (Borry et al., 2021), but these methods have not been designed, nor can they be computationally upscaled to calculate the thousands of taxonomic species that occur in just one metagenome.

²² **2. Methods** We present metaDMG, a novel framework that takes advantage of the information already contained in the alignment files to compute and statically evaluate post-mortem DNA damage, thus bypassing the need for classifying and splitting reads into individual organisms and realigning these to parse data to mapDamage2.0 (Jónsson et al., 2013). It

uses a Bayesian approach that combines a geometric damage profile with a beta-binomial model to fit the entire model to the misincorporations which drastically improve the damage estimates compared to previous methods.

30 **3. Results** Using a two-tier simulation setup, we find `metaDMG` to not only be a factor of 10 faster than previous methods but it is also more accurate and able to evaluate even complex metagenomes with tens of thousands of species. Even with very few number of reads, down to even below 1000 reads. BLABLA, more results here.

34 **4. Conclusion** `metaDMG` includes state-of-the-art statistical methods for computing nucleotide misincorporation and fragmentation patterns of even highly complex samples along with re-implementation of the current statistics used within the field such as PMDtools (Skoglund et al., 2014). This suite of programs is freely available and consists of computational parts implemented as multi threaded C++ programs as well as computationally optimized modern python libraries, and an interactive dashboard for displaying the results. `metaDMG` is furthermore flexible, compatible with custom databases, can output nucleotide misincorporation and fragmentation patterns at different taxonomic ranks as well as per reference ID.

46 1 | INTRODUCTION

Throughout the life of an organism, it contaminates its surrounding environment with cells or
48 tissue and hence its DNA contained within. As the cell leaves its host, DNA repair mechanisms
stop and the DNA is now subjected to chemical and mechanical degradation, resulting in frag-
50 mented molecules and chemical damages, characteristic for ancient DNA (Briggs et al., 2007; Dab-
ney, Meyer, and Pääbo, 2013). Ancient DNA has been shown to be able to survive in the envi-
52 ronment for thousands and even up to two million years (Kjaer et al in review), and have been
widely used to study past organisms and organism composition (Cappellini et al., 2018). Partic-
54 ularly misincorporations of cytosines on thymines as a result of deamination has been found to
independently authenticate ancient DNA origin (Dabney, Meyer, and Pääbo, 2013; Ginolhac et al.,

56 2011). Postmortem damage with regards to DNA is characterized by the four Briggs parameters
57 (Briggs et al., 2007). A damaged dna fragment tend to be short, and is likely to be single stranded
58 at the termini of the fragment. There is an high proportion of C→T substitutions at the single
59 stranded part ϵ_{ss} , a somewhat higher C→ T at the double stranded part ϵ_{ds} . The length of the sin-
60 gle stranded part (*overhang*) follows a geometric distribution λ , and finally there might be breaks at
61 the backbone in the double stranded part v . It is possible to estimate these four Briggs parameters
62 Jónsson et al., 2013 but these four parameters are rarely used directly for asserting "ancientness",
63 and researchers working with ancient DNA tend to simply use the empirical C→T on the first po-
64 sition of the fragment together with other supporting summary statistic of the experiment. This
65 ancient DNA (aDNA) authenticity approach, were initially performed on single individual sources
66 such as hair, bones, teeth and later on ancient environmental samples such as soil sediments CITE
67 SOMETHING. While this is a relatively fast process for single individuals it becomes increasingly
68 demanding, iterative and time consuming as the samples and the diversity within increases, as in
69 the case for metagenomes from ancient soil, sediments, dental calculus, coprolites and other an-
70 cient environmental sources. It has therefore been practice to estimate damage for only the key
71 taxa of interest in a metagenome, as a metagenomic sample easily includes thousands of different
72 taxonomic entities, that would make a complete estimate an impossible task.

We have devised a novel test statistic in `metaDMG` which takes into account all relevant infor-
74 mation in single scalar. For these reasons, we present here `metaDMG`, a tool that enables fast and
75 accurate DNA damage estimation of whole metagenomes within hours. `metaDMG` is designed and
76 upscales equally for the increasingly large datasets that are generated in the field of ancient envi-
77 ronmental DNA, but can also with advantage be used to estimate DNA damage of single genomes
78 and samples with low complexity, it can even compute an global damage estimate for a given sam-
79 ple. `metaDMG` is compatible with the NCBI taxonomy and can use `ngsLCA` to perform a naïve last
80 common ancestor of the aligned reads to get precise damage estimates for the reads classified to
81 different taxonomic nodes. In addition, it is also designed to be used with custom taxonomies and
82 metagenomic assembled genomes.

After defining the method and notation used throughout this paper, we show through multi-
84 ple sets of simulations that `metaDMG` not only improves on existing methods in the case of single-
85 genome damage estimation but also work for metagenomic samples. Finally, we apply our method
86 on a representative mix of nine different metagenomic samples to show the real life performance

of metaDMG.

2 | METHODS & MATERIALS

Perhaps the most basic bioinformatic analyses is the difference between two nucleotide sequences.

This assumes that we have a haploid representation of our target organisms and larger differences can be interpreted as larger genetic differences. Obtaining a haploid representation is none trivial, firstly our target organism might not be haploid and we need to construct a consensus genome, secondly data from modern day sequencers are essentially a sampling with replacement process and we need to infer the relative location of each of the possible millions or even billions of short DNA fragments, this is the process which is called mapping or alignment. Thirdly, and the focus for this manuscript, is the quantification of the presence of postmortem damage (PMD) in DNA. PMD mainly manifests as an excess of cytosine to thymine substitutions at the termini of fragments that has been prepared for sequencing. A priori we can not directly observe these actual biochemical changes but we can align each fragment and consider the difference between reference and read as possible PMD, and it is even possible to use the excess of C to T at the single fragment level to separate modern from ancient (data with PMD) (Skoglund et al., 2014). Expanding from the single read all reads for a sequencing experiment and genome to tabulate the overall substitution or mismatch rates to obtain a statistic of the damage (Borry et al., 2021) or even estimate the four Briggs parameters that is traditionally used to characterize the damage signal (Jónsson et al., 2013).

We have devised a general ancient DNA damage toolkit with a special emphasis in a metagenomic setting which implements and expands existing relevant methods but also expands with several state of the art novel methodologies. At the most basic level we have reimplemented the approach given in (Skoglund et al., 2014) which allows for the extracting and separation of highly damaged DNA reads. Secondly under the assumption of vast amounts of data we have defined a full multinomial regression model building on the method in (Cabanski et al., 2012), we show that this will give superior and stable results if it is possible to obtain high depth and coverage data. However in standard ancient DNA context it is generally not possible to obtain vast amounts of data and we propose two novel tests statistics that is especially suited for this scenario. To our knowledge there are no currently available methods that is geared towards damage analysis in a metagenomic setting and existing approaches are essentially based on remapping against the sin-

¹¹⁶ gle target organism and does not take into account any possible issues with regards to reads being
¹¹⁷ well assigned or specified. Our solution called metaDMG (pronounced metadamage), estimates the
¹¹⁸ damage patterns in metagenomic samples in a three step approach. First, the lowest common
¹¹⁹ ancestor (LCA) for each read (mapped to a multi-species reference database) is computed and the
¹²⁰ the mismatch matrix for each leaf node (e.g. taxonomic ID or contig, depending on the database
¹²¹ used) is computed based on the mapped reads. Second, metaDMG fits a damage model to each leaf
¹²² node to compute the ancient damage estimates. Finally, the results are visualized in the metaDMG
¹²³ dashboard, which is a state of the art graphical user interface that allows for fast and user-friendly
¹²⁴ interaction with the results for further downstream analysis and visualization.

2.1 | Lowest Common Ancestor and Mismatch matrices

¹²⁶ For environmental DNA (eDNA) studies we routinely apply a competitive alignment approach where
¹²⁷ we consider all possible alignments for a given read. Each read is mapped against a multi species
¹²⁸ reference databases (e.g. nucleotide or RefSeq from NCBI or custom downloaded). A single read
¹²⁹ might map to a highly conserved gene that is shared across higher taxonomic ranks such as class
¹³⁰ or even domains. This read will not provide relevant information due to the generality, whereas a
¹³¹ read that maps solely to a single species or species from a genus would be indicative of the read
¹³² being well classified. We seek to obtain the pattern or signal of damage which is done by the tab-
¹³³ ulation of the cycle specific mismatch rates between our reference and observed sequence for all
¹³⁴ well classified reads.

In details we compute the lowest common ancestor (lca) for all alignments for each read, this
¹³⁶ is done using (Wang et al., 2022) and if a read is well classified or properly assigned based on a user
¹³⁷ defined threshold (species, genus or family) we tabulate the mismatches for each cycle, if a read is
¹³⁸ not well assigned it is discarded. Pending on the run mode we allow for the construction of these
¹³⁹ mismatch tables on three different levels. Either we obtain a basic single global mismatch matrix,
¹⁴⁰ which could be relevant in a standard single genome aDNA study and similar to the tabulation used
¹⁴¹ in (Jónsson et al., 2013). Secondly we can obtain per reference counts or if a taxonomy database
¹⁴² has been supplied we allow for the aggregation from leaf nodes to the internal taxonomic ranks
towards the root.

¹⁴⁴ To suit as many users as possible, metaDMG takes as input an alignment file (.bam, .sam, or
.sam.gz), where Each read is hereafter allowed an equal chance to map against the multiple refer-

¹⁴⁶ ences. One read can therefore attract multiple alignments, and we thus first seek to find the lowest common ancestor (LCA) among the alignments based on the tree structure from the databases and
¹⁴⁸ a user defined read-reference similarity interval (Wang et al., 2022). Note that metaDMG is not limited to the NCBI database and allow for custom databases as well.

¹⁵⁰ Regardless of runmode or weighing scheme used in the possible aggregation we obtain the nucleotide substitution frequencies across reads which provides us with the position dependent
¹⁵² mismatch matrices, $\underline{M}(x)$, with x denoting the position in the read, starting from 1. At a specific position, $M_{ref \rightarrow obs}(x)$ describes the number of nucleotides that was mapped to a reference base B_{ref}
¹⁵⁴ but observed to be B_{obs} , where $B \in \{A, C, G, T\}$. The number of C to T transitions, e.g., is denoted as $M_{C \rightarrow T}(x)$.

¹⁵⁶ When calculating the mismatch matrix, two different approaches can be taken. Either all alignments of the read will be counted, which we will refer to as weight-type 0, or the counts will be
¹⁵⁸ normalized by the number of alignments of each read; weight-type 1 (default).

2.2 | Damage Estimation

¹⁶⁰ The damage pattern observed in aDNA has several features which are well characterized. By modelling these, one can construct observables sensitive to aDNA signal. We model the damage patterns seen in ancient DNA by looking exclusively at the $C \rightarrow T$ transitions in the forward direction (5') and the $G \rightarrow A$ transitions in the reverse direction (3'). For each LCA, we denote the number of
¹⁶⁴ transitions $k(x)$ as:

$$k(x) = \begin{cases} M_{C \rightarrow T}(x) & \text{for } x > 0 \quad (\text{forward}) \\ M_{G \rightarrow A}(x) & \text{for } x < 0 \quad (\text{reverse}) \end{cases} \quad (1)$$

¹⁶⁶ and the number of the reference counts $N(x)$:

$$N(x) = \begin{cases} \sum_{i \in B} M_{C \rightarrow i}(x) & \text{for } x > 0 \quad (\text{forward}) \\ \sum_{i \in B} M_{G \rightarrow i}(x) & \text{for } x < 0 \quad (\text{reverse}), \end{cases} \quad (2)$$

¹⁷⁰ where the sum is over all four bases. The damage frequency is thus $f(x) = k(x)/N(x)$. A natural choice of likelihood model would be the binomial distribution. However, we found that a binomial
¹⁷² likelihood lacks the flexibility needed to deal with the large amount of variance (overdispersion) we found in the data due to bad references and misalignments.

¹⁷⁴ To accommodate overdispersion, we instead apply a beta-binomial distribution, $\mathcal{P}_{\text{BetaBinomial}}$, which
^{1 Note that we do not parameterize the beta distribution in terms of the common (α, β) parameterization, but instead using the more intuitive (μ, ϕ) parameterization. One can re-}
¹⁷⁶ treats the probability, p , as a random variable following a beta distribution¹ with mean μ and con-
^{centration ϕ : $p \sim \text{Beta}(\mu, \phi)$. The beta-binomial distribution has the the following probability density}
¹⁷⁸ function:
¹⁸⁰

$$\mathcal{P}_{\text{BetaBinomial}}(k | N, \mu, \phi) = \binom{N}{k} \frac{B(k + \mu\phi, N - k + \phi(1 - \mu))}{B(\mu\phi, \phi(1 - \mu))}, \quad (3)$$

where B is defined as the beta function:

$$B(x, y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)}, \quad (4)$$

¹⁸² with $\Gamma(\cdot)$ being the gamma function (Cepeda-Cuervo and Cifuentes-Amado, 2017).

¹⁸⁴ Amado, 2017).

The close resemblance to a binomial model is most easily seen by comparing the mean and

variance of a random variable k following a beta-binomial distribution, $k \sim \mathcal{P}_{\text{BetaBinomial}}(N, \mu, \phi)$:

$$\begin{aligned} \mathbb{E}[k] &= N\mu \\ \mathbb{V}[k] &= N\mu(1-\mu) \frac{\phi+N}{\phi+1}. \end{aligned} \quad (5)$$

The expected value of k is similar to that of a binomial distribution and the variance of the beta-

¹⁸⁶ binomial distribution reduces to a binomial distribution as $\phi \rightarrow \infty$. The beta-binomial distribution
¹⁸⁸ can thus be seen as a generalization of the binomial distribution.

¹⁹⁰ Note that both equation (3) and (5) relates to damage at a specific base position, i.e. for a single
¹⁹² k and N . To estimate the overall damage in the entire read using the position dependent counts,
¹⁹⁴ $k(x)$ and $N(x)$, we model μ as position dependent, $\mu(x)$, and assume a position-independent concen-
¹⁹⁶ tration, ϕ . We model the damage frequency with a modified geometric sequence, i.e. exponential
^{decreasing for discrete values of x :}

$$\tilde{f}(x; A, q, c) = A(1-q)^{|x|-1} + c. \quad (6)$$

¹⁹⁶ Here A is the amplitude of the damage and q is the relative decrease of damage pr. position. A
¹⁹⁸ background, c , was added to reflect the fact that the mismatch between the read and reference
²⁰⁰ might be due to other factors than just ancient damage. As such, we allow for a non-zero amount
^{of damage, even as $x \rightarrow \infty$. This is visualized in Fig. 1 along with a comparison between the classical}
^{binomial model and the beta-binomial model.}

²⁰² To estimate the fit parameters, A , q , c , and ϕ , we apply Bayesian inference to utilize domain
^{specific knowledge in the form of priors. We assume weakly informative beta-priors² for both A , q ,}

² Parameterized as (μ, ϕ)

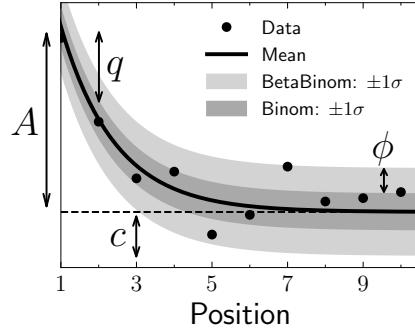

Figure 1. Illustration of the damage model. The figure shows data points as circles and the damage, $f(x)$, as a solid line. The amplitude of the damage is A , the offset is c , and the relative decrease in damage pr. position is given by q . The damage uncertainty for a binomial model is shown in dark grey and the uncertainty for a beta-binomial model in light grey. The additional uncertainty of the beta-binomial model, compared to the binomial model, is related to ϕ , see equation (5).

204 and c . In addition to this, we assume an exponential prior on ϕ with the requirement of $\phi > 2$ to
205 avoid too much focus on 0-or-1 probabilities (McElreath, 2020). The final model is thus:

$$\begin{aligned}
 206 \quad [A \text{ prior}] \quad & A \sim \text{Beta}(0.1, 10) \\
 207 \quad [q \text{ prior}] \quad & q \sim \text{Beta}(0.2, 5) \\
 208 \quad [c \text{ prior}] \quad & c \sim \text{Beta}(0.1, 10) \\
 209 \quad [\phi \text{ prior}] \quad & \phi \sim 2 + \text{Exponential}(1000) \\
 210 \quad [\text{likelihood}] \quad & k_i \sim P_{\text{BetaBinomial}}(N_i, \tilde{f}(x_i; A, q, c), \phi),
 \end{aligned} \tag{7}$$

212 where i is an index running over all positions.

213 We define the damage due to deamination, D , as the background-subtracted damage frequency
214 at the first position: $D \equiv \tilde{f}(|x| = 1) - c$. As such, D is the damage related to ancientness. Using the
215 properties of the beta-binomial distribution, eq. (5), we find the mean and variance of the damage,

216 D :

$$\begin{aligned}
 217 \quad \mathbb{E}[D] & \equiv \bar{D} = A \\
 218 \quad \mathbb{V}[D] & \equiv \sigma_D^2 = \frac{A(1-A)}{N} \frac{\phi + N}{(\phi + 1)}.
 \end{aligned} \tag{8}$$

219 Since D estimates the overexpression of damage due to ancientness, not only the mean is
220 relevant but also the certainty of $D > 0$. We quantify this through the significance $Z = \bar{D}/\sigma_D$

²²⁰ which is thus the number of standard deviations ("sigmas") away from zero. Assuming a Gaussian distribution of D , $Z > 2$ would indicate a probability of D being larger than zero, i.e. containing ancient damage, with more than 97.7% probability. These two values allows us to not only quantify the amount of ancient damage (ie. \bar{D}) but also the certainty of this damage (Z) without even having to run multiple models and comparing these.

We perform the Bayesian inference of the parameters models using Hamiltonian Monte Carlo (HMC) sampling which is a particular of Monte Carlo Markov Chain (MCMC) algorithm (Betancourt, 2018). Specifically, we use the NUTS implementation in NumPyro (Phan, Pradhan, and Jankowiak, 2019), a Python package which uses JAX (Bradbury et al., 2018) under the hood for automatic differentiation and JIT compilation. We treat each leaf node of the LCA as being independent and generate 1000 MCMC samples after an initial 500 samples as warm up.

Since running the full Bayesian model is computationally expensive, we also allow for a faster, approximate method by just fitting the maximum a posteriori probability (MAP) estimate. We use iMinuit (Dembinski et al., 2021) for the MAP optimization with Numba acceleration (Lam, Pitrou, and Seibert, 2015) for even faster run times. On a Macbook M1 Pro model from 2021, the timings for running the full Bayesian model is 1.41 ± 0.04 s/fit and for the MAP it is 4.34 ± 0.07 ms/fit, showing more than a 2 order increase in performance (around 300x) for the approximate model. Both models allow for easy parallelisation to decrease the computation time.

²³⁸ 2.3 | Visualisation

We provide an interactive dashboard to properly visualise the results from the modelling phase, see <https://metadm.onrender.com/> for an example. The dashboard allows for filtering, styling and variable selection, visualizing the mismatch matrix related to a specific leaf node, and exporting of both fit results and plots. By filtering, we include both filtering by sample, by specific cuts in the fit results (e.g. requiring D to be above a certain threshold), and even by taxonomic level (e.g. only looking tax IDs that are part of the Mammalia class). We greatly believe that a visual overview of the fit results increase understanding of the data at hand. The dashboard is implemented with Plotly plots and incorporated into a Dash dashboard (Plotly, 2015).

3 | SIMULATION STUDY

248 We conducted two sets of simulations, one to gauge the performance of the damage model itself
250 and one to determine the performance of the full metaDMG pipeline, i.e. both LCA and damage
model.

3.1 | Single-genome Simulations

252 The first set of simulations was performed by taking a single, representative genome and adding
254 deamination and sequencing noise to it followed by a mapping step and finally damage estima-
256 tion using metaDMG. The deamination was applied using NGSNGS (XXX, ref here) which is a recent
258 implementation of the original Briggs model similar to Gargammel (Neukamm, Peltzer, and Nieselt,
n.d.) but with better performance and more accurate deamination patterns. In this step we vary
the simulated amount of damage added (in particular the single-stranded DNA deamination, δ_{ss})
260 in the original Briggs model (Briggs et al., 2007)), the number of reads, and the fragment length
distribution.

262 We chose five different, representative genomes, in each of these varying the three simulation
parameters. These genomes where the homo sapiens, the betula, and three microbial organisms
264 with respectively low, median, and high amount of GC-content. For each of these simulations,
we performed 100 independent runs to measure the variability of the parameter estimations and
266 quantify the robustness of the estimates. We simulated eight different sets of damage (approxi-
mately 0%, 1%, 2%, 5%, 10%, 15%, 20%, 30%), 13 sets of different number of reads (10, 25, 50, 100, 250,
268 500, 1.000, 2.500, 5.000, 10.000, 25.000, 50.000, 100.000), three sets of different fragment length distri-
butions (samples from a lognormal distributions with mean 35, 60, and 90, each with a standard
270 deviation of 10), and five different genomes, each simulation set repeated 100 times.

272 In addition to this, we also create 1000 repetitions of the non-damaged simulations for Homo
Sapiens to be able to gauge the risk of finding false positives. Finally, to show that the damage esti-
274 mates that metaDMG provides are independent of the contig size, we artificially create three different
genomes by sampling 1.000, 10.000 or 100.000 different basepairs from a uniform categorical dis-
tribution of {A, C, G, T}.

276 To be able to compare our estimates to a known value, we generate 1.000.000 reads from
NGSNGS without any added sequencing noise for each of other sets of simulation parameters.

²⁷⁶ The difference in damage frequency at position 1 and 15 is then the value to compare to:

$$D_{\text{known}} = \frac{f(x=1) - f(x=15)}{2} + \frac{f(x=-1) - f(x=-15)}{2}, \quad (9)$$

²⁷⁸ where we take the average of the C to T damage frequency difference and the G to A damage frequency difference.

²⁸⁰ The fastq files were simulated with NGSNGS using the above mentioned simulation parameters, all with the same quality scores profiles as used in ART (Huang et al., 2012), based on the Illumina ²⁸² HiSeq 2500 (150 bp). The mapping was performed using Bowtie-2 with the `-no-unal` flag (Langmead and Salzberg, 2012).

²⁸⁴ 3.2 | Metagenomic Simulations

²⁸⁶ While the previously mentioned simulation study is perfectly aimed at quantifying the performance of the damage model in the case of single-reference genomics it does lack the complexity related to metagenomic samples. Therefore, we also conduct a more advanced simulation study to determine the accuracy of the full ²⁸⁸ `metaDMG` pipeline.

The previously mentioned simulation study quantifies the damage model's performance for ²⁹⁰ single-reference genomics, but it does not address the complexity of metagenomic samples. Therefore, we also conducted a more advanced simulation study to determine the accuracy of the full ²⁹² `metaDMG` pipeline. Based on an ancient metagenome, we created a synthetic dataset that reproduces the composition, fragment length distribution, and damage patterns for each genome. We ²⁹⁴ selected X metagenomes (Supp table XXX) covering several environmental conditions and ages. First, we mapped the reads of each metagenome with bowtie2 against a database that contained ²⁹⁶ the GTDB r202 (Parks et al., 2018) species cluster reference sequences, all organelles from NCBI RefSeq (NCBI Resource Coordinators, 2018), and the reference sequences from CheckV (Nayfach ²⁹⁸ et al., 2021). We used `bam-filter 1.0.11` with the flag `--read-length-freqs` to get the mapped read length distribution for each genome and their abundance. The genomes with an observed-to-³⁰⁰ expected coverage ratio greater than 0.75 were kept. The filtered BAM files were processed by `metaDMG` to obtain the misincorporation matrices. The abundance tables, fragment length distribution, and misincorporation matrices were used in aMGSIM-smk v0.0.1 (Fernandez-Guerra, 2022), a ³⁰² Snakemake workflow (Mölder et al., 2021) that facilitates the generation of many synthetic ancient metagenomes. The data used and generated by the workflow can be obtained from Figshare link ³⁰⁴

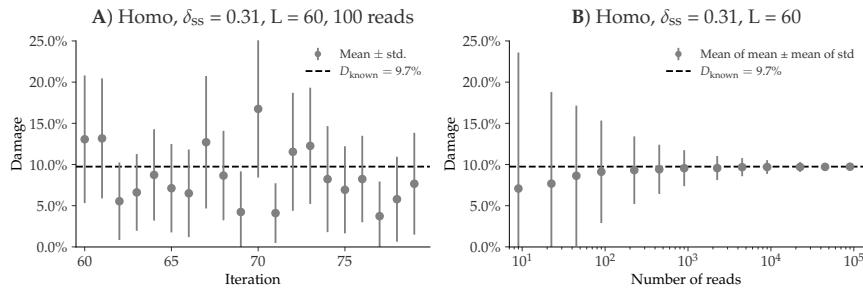

Figure 2. Overview of the single-genome simulations based on the homo sapiens genome with the Briggs parameter $\delta_{SS} = 0.065$ and a fragment length distribution with mean 60. **A)** This plot shows the estimated damage (D) of 10 simulations with 100 simulated reads. The grey points shows the mean damage (with its standard deviation as errorbars). The known damage (D_{known}) is shown as a dashed line, see eq. (9). **B)** This plot shows the average damage as a function of the number of reads. The grey points show the average of the individual means (with the average of the standard deviations as errors).

(XXX). We then performed taxonomic profiling using the same parameters used for the synthetic
306 reads generated by aMGSIM-smk.

4 | RESULTS

308 The accuracy of all methods in metaDMG was tested in various simulation scenarios. In general we
find that metaDMG yields accurate, precise damage estimates even in extreme low-coverage data.

310 4.1 | Single-genome Simulations

The results of the single-genome simulations can be seen in Figure 2. The left part of the figure
312 shows metaDMG damage estimates based on the homo sapiens genome with the Briggs parameter
 $\delta_{SS} = 0.31$ and a fragment length distribution with mean 60, each of the 10 simulations generated
314 with 100 simulated reads for 10 representative simulations. When the damage estimates are low,
the distribution of D is highly skewed (restricted to positive values) leading to errorbars sometimes
316 going into negative damage, which of course represents un-physical values. The right hand side of
the figure visualizes the average amount of damage across a varying number of reads. This shows
318 that the damage estimates converge to the known value with more data, and that one needs more
than 100 reads to even get strictly positive damage estimates (when including uncertainties).

320 Across more than 5 different species, 3 different fragment length distributions, and 3 different

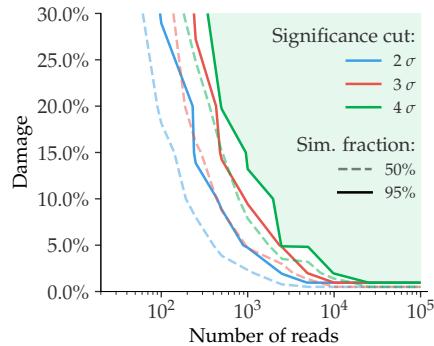

Figure 3. Given a specific significance cut, the solid contour line shows the relationship between the amount of damage and the number of reads required to be able to correctly infer damage in 95% of the species. The dashed line shows the similar value for a simulation fraction of 50%. The green part of the figure shows the “good” region of number of reads and estimated damage, given than one wants to be more than 95% certain of correctly identifying damage with more than 4σ confidence.

contig length distributions, each with 100 simulations for 104 different sets of simulation parameters, the only difference we note in the damage estimates is between species with low, median, and high GC-levels. In general, species with higher GC-levels exhibit lower variations in their damage estimates compared to species with lower GC-levels, leading to high-GC species requiring fewer reads to establish damage estimates.

Based on the single-genome simulations, we can compute the relationship between the amount of damage in a species and the number of reads required to correctly infer that the given species is damaged, see Figure 3. If we want to find damage with a significance of more than 2 (solid blue line) in a sample with around 5% expected damage, it requires about 1000 reads to be 95% certain that we will find results this good. Said in other words: given 100 different samples, each with 1000 reads and around 5% damage, one would expect to find damage (with a $Z > 2$) in 95 of the total 100 samples, on average. If we loose the requirement such that it is okay to only find it in every second sample, it would be enough with only around 250 reads in each sample (dashed blue line).

Finally, to quantify the risk of incorrectly assigning damage to a non-damaged species, we created 1000 independent simulations for a varying number of reads, where none of them had any artificial ancient damage applied, only sequencing noise. Figure 4 shows the damage (D) as a function of the significance (Z) for the case of 1000 simulated reads. Even though the estimated damage is larger than zero, the damage is non-significant since the significance is less than one. When looking

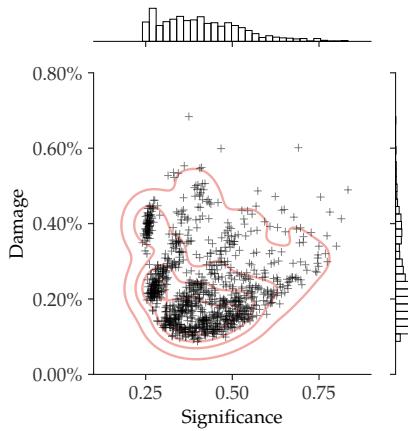

Figure 4. This figure shows the inferred damage estimates of 1000 independent simulations, each with 1000 reads and no artificial ancient damage applied, with the inferred damage shown on the y-axis and the significance on the x-axis. Each simulation is shown as a single cross and the red lines show the kernel density estimate (KDE) of the damage estimates. The marginal distributions are shown as histograms next to the scatter plot.

at all the figures across the different number of reads, see Figure bayesian_zero_damage_plots.pdf,

340 we note that a loose cut requiring that $D > 1\%$ and $Z > 2$ would filter out all of non-damaged points.

342 4.2 | Metagenomic Simulations

With the full metagenomic simulation pipeline we can further probe the performance of metaDMG.

344 By looking at the six different samples at different steps in the pipeline we are able to show that
 346 metaDMG provides relevant, accurate damage estimates. First of all, we run metaDMG on the six samples after fragmentation with FragSim. Since no deamination has yet been added at this step in the
 348 pipeline, this is also a test of the risk of getting false positives. The results can be seen in Figure 5 where we see the damage estimates for both the species that we simulate to be ancient and the species that we do not add deamination to. We see that the damage estimates are quite similar,
 350 as expected, and that our previously established loose cut of $D > 1\%$ and $Z > 2$ still filters out all of non-damaged points.

352 In comparison we can look at Figure 6 which shows the same plot, but after the deamination (deamSim) and sequencing errors (ART) has been added. Here we see a clear difference between

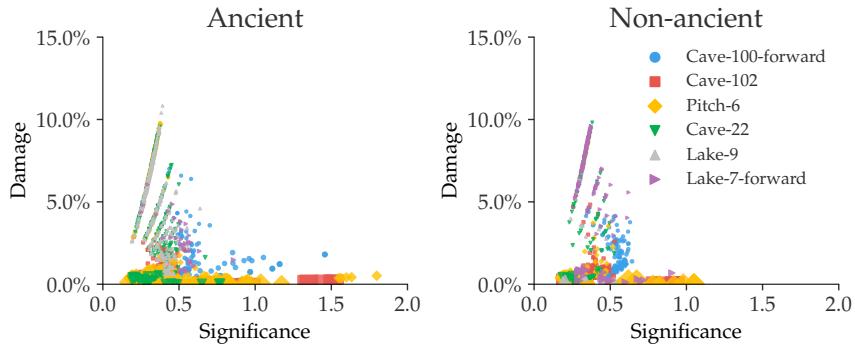

Figure 5. Estimated amount of damage as a function of significance using the fragSim data. The left figure shows the damage of the species that we simulated to be ancient (however with no deamination added yet) and the right figure shows the same for the species that are not going to have deamination added.

354 the ancient and the non-ancient ones, as expected. The non-ancient species would still not pass
 355 the loose cut, however, we note that a large number of the ancient samples would. By looking at
 356 Figure 6 we see that not all of the samples show similar amount of damage. These observations
 357 are summarised in Table 1 where we see that Cave-100-forward, Cave-102, Pitch-6 all have more
 358 than 60% of their ancient species labelled as damaged according to the loose cut, Cave-22 (18%)
 359 and Lake-7-forward (12%) a bit lower, while Lake-9 (0.5%) does not show any clear signs of damage.
 360 However, once we condition on the requirement of having more than 100 reads, the fraction of
 361 ancient species correctly identified as ancient increases to more than 90% for most the samples.
 362 To better understand the damage estimates, we can look a them individually. Figure 7 shows
 363 the *Stenotrophomonas maltophilia* species from the Pitch-6 sample. We see that none of the
 364 fragmentation-only files were estimated to have damage and that most of the deamination and
 365 final files including sequencing errors have damage – at a simulation size of 1 million, the signif-
 366 icance of both are $Z \approx 1.9$, so this one of the few fits with more than 100 reads that does not
 367 pass the loose cut. Furthermore, we notice that the error bars decrease with simulation size, as
 368 expected.

The rest of the metagenomic simulation results are shown in Figure XXX.

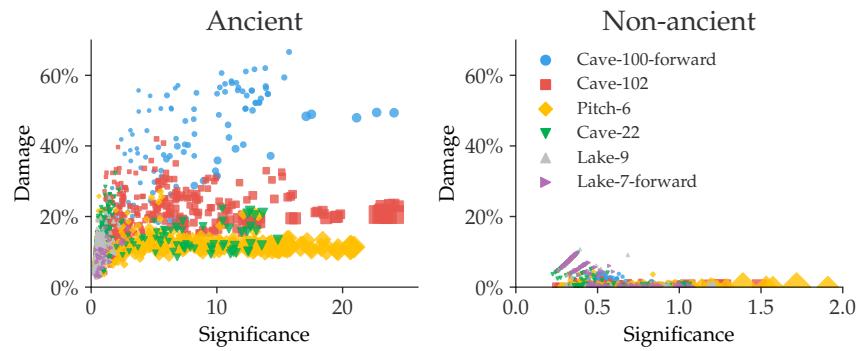

Figure 6. Estimated amount of damage as a function of significance using the ART data. The left figure shows the damage of the species that we simulated to be ancient and the right figure shows the same for the species that have not had deamination added.

Table 1. Number of ancient species for each of the six simulated samples. The first column is the total number of species, the second column is the total number of species that would pass the loose cut of $D > 1\%$ and $Z > 2$, the third column is the number of species with more than 100 reads, and the final column is the number of species with more than 100 reads that also do pass the cut.

Sample	Total	Pass	+100 Reads	+100 Reads and Pass
Cave-100-forward	135	107	79.3%	88
Cave-102	500	326	65.2%	309
Pitch-6	415	260	62.7%	274
Cave-22	393	71	18.1%	73
Lake-9	410	2	0.5%	8
Lake-7-forward	32	4	12.5%	6

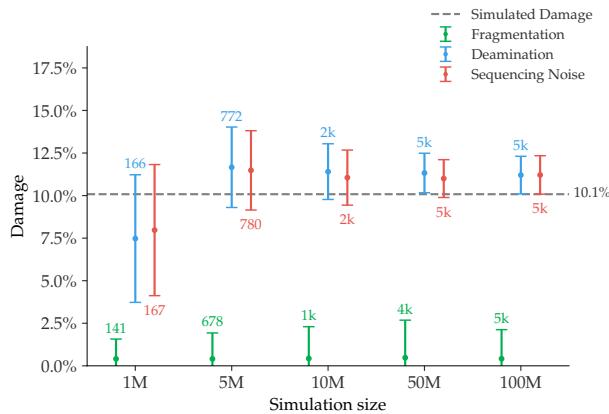

Figure 7. Damage estimates of the *Stenotrophomonas maltophilia* species from the Pitch-6 sample. Damage is shown as a function of simulation size, with the fragmentation files in green, the deamination files in blue and the final files including sequencing errors in red. All errors are 1σ error bars (standard deviation). The number of reads for each fit is shown as text and since this was a species simulated to have ancient damage, the simulated amount of damage is shown as a dashed grey line.

370 4.3 | Real Data

The results from running the full metaDMG pipeline on real data can be seen in Figure 8. The figures
 372 shows Blablabla, real life data here. We find that the loose cut ($D > 1\%$, $Z > 2$) accepts only one of
 the fits from the control test Library-0, which would not have been accepted by more conservative
 374 cut ($D > 2\%$, $Z > 3$, more than 100 reads).

4.4 | Bayesian vs. MAP

376 Due to increased computational burden of running the full Bayesian model compared to faster,
 approximate MAP model, in samples with several thousand species, the MAP model is often the
 378 most realistic model to use due to time constraints. In this case, it is of course important to know
 that the damage estimates are indeed trustworthy. Figure 9 compares the estimated damage
 380 between the Bayesian model and the MAP model and the estimated significances for species with
 $D > 1\%$, $Z > 2$ and more than 100 reads. The figure shows that the vast majority of species map
 382 1:1 between the Bayesian and the MAP model. One should note, though, that the few species with
 the highest mismatch, all are based on forward-only fits, i.e. with no information from the reverse
 384 strand, which thus leads to less data to base the fits on. For the comparison with no cuts, see

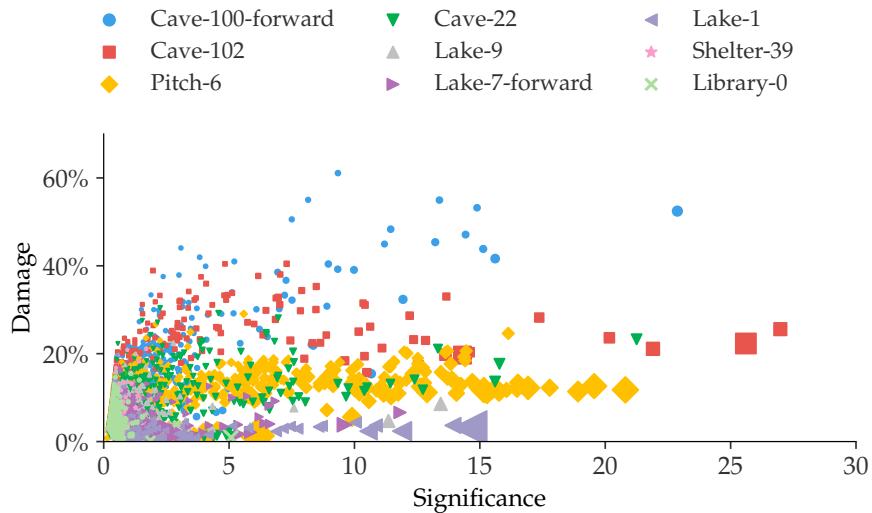

Figure 8. Estimated amount of damage as a function of significance using the real data.

Figure 1 in appendix.

386 4.5 | Existing Methods

We have also compared `metaDMG` to existing methods such as PyDamage (Borry et al., 2021). Since

388 PyDamage does not include the LCA step, this comparison is based on the non-LCA mode (local-mode) of `metaDMG`. This mode iterates through the different assigned species for all mapped reads
390 and estimates the damage for each. In general, we find that `metaDMG` is more conservative, accurate
and precise in its damage estimates.

392 An example of this is can be found in Figure 10, which shows both the `metaDMG` and PyDamage
results of the 100 *Homo Sapiens* single-genome simulations with 100 reads and 15% added artificial
394 damage (and a fragment length distribution with mean 60).

To compare the computational performance, we use the Pitch-6 sample which has 11.433
396 unique taxa. When using only a single core, PyDamage took 1105 s to compute all fits, while `metaDMG`
took 88 s, a factor of 12.6x faster. Out of the 88 s, `metaDMG` spent 53 s on the actual fits, the rest was for
398 loading and reading the alignment file and computing the mismatch matrices. This makes `metaDMG`
more than 20x faster than PyDamage for the fit computation. For the rest of the timings, see Ta-
400 ble 2. PyDamage requires the alignment file to be sorted by chromosome position and be supplied
with an index file, allowing it to iterate fast through the alignment file, at the expense of computa-

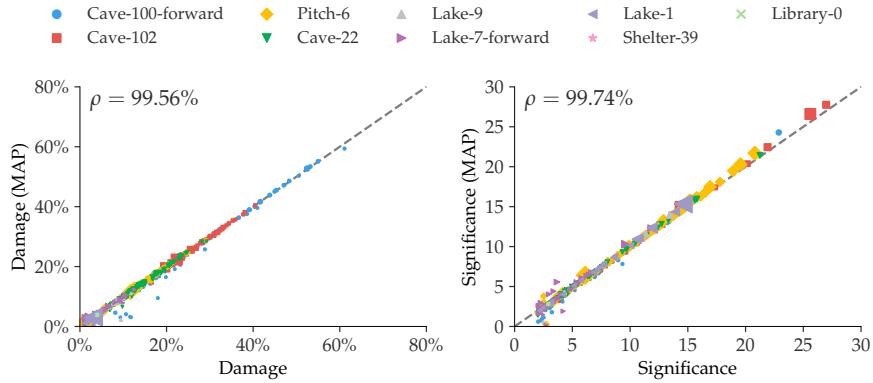

Figure 9. Comparison between the full Bayesian model and the fast, approximate, MAP model for the estimated damage and significance. The figure shows data after a loose cut of $D > 1\%$, $Z > 2$ and more than 100 reads. The dashed, grey line shows the 1:1 ratio and the correlation, ρ , is shown in the upper right corner.

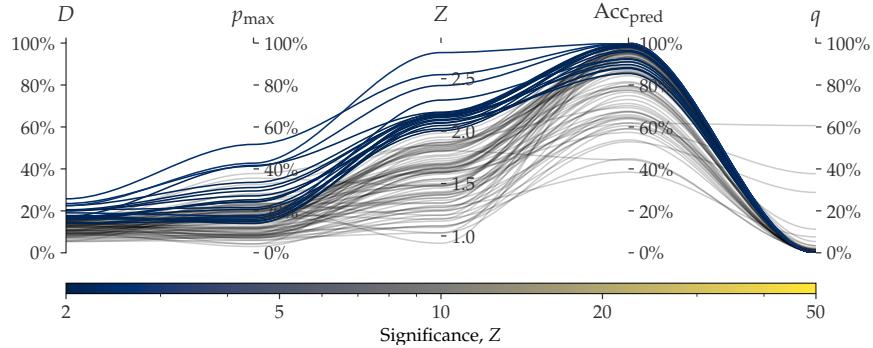

Figure 10. Parallel Coordinates plot comparing metaDMG and PyDamage for the *Homo Sapiens* single-genome simulation with 100 reads and 15% added artificial damage. The different axis shows the five different variables: metaDMG-damage (D , by metaDMG), PyDamage-damage (p_{max} , by PyDamage), significance (Z , by metaDMG), predicted accuracy (Acc_{pred} , by PyDamage), and the p-value (q , by PyDamage). Each of the 100 simulations are plotted as single lines showing the values of the different dimensions. Simulations with $D > 1\%$ and $Z > 2$, i.e. damaged according to the loose metaDMG cut, are shown in color proportional to their significance. Non-damaged simulations are shown in semi-transparent black lines.

Table 2. Computational performance of PyDamage and metaDMG. The table contains the times it takes to run either PyDamage or metaDMG on the full Pitch-6 sample containing 11.433 species. The timings are shown for both single-processing case (1 core) and multi-processing (2 and 4 cores). The timings were performed on a Macbook M1 Pro model from 2021. “12.6x” means that metaDMG was 12.6 times faster than PyDamage for that particular test.

Cores	Pitch-6		Pydamage		metaDMG	
	Total	Fits	Total	Fits		
1	1105 s	1102 s	88 s	12.6x	53 s	20.8x
2	592 s	590 s	66 s	9.0x	25 s	23.6x
4	398 s	397 s	54 s	7.4x	14s	28.4x

tional load before running the actual damage estimation. metaDMG on the other hand requires the reads to be sorted by name to minimize the time it takes to run the LCA, which however, is not tested in this comparison.

5 | DISCUSSION

Preliminary work indicates that the computational performance of the models can be even further optimized by using Julia (Bezanson et al., 2017), which shows around 7x optimization for the Bayesian model (~ 0.2 s/fit) and 4x for the MAP model (~ 1.1 ms/fit).

Appendix 3

C | LIKELIHOOD CALCULATION

C.1 | Full multinomial logistic Regression models

514 Postmortem damages will have impacts on the NGS (next generation sequencing) reads.

516 A common phenomenon is the calling error rates increases from nucleotide C to T due to
518 the cytosine deamination process. Unawareness of this will lead to inaccurate inferences.

520 Evidences show that the magnitude of such changes are related to the positions the site is
522 within a read (the fraction of the ancient DNA). Here we present 3 slightly different ways to
unveil the relationship between the calling error rates and the mismatching reference/read
pairs as well as the site positions within a read. The methods are based on the multinomial
logistic regressions.

524 Data Description

526 We perform the regression based on the summary statistic of the mismatch matrix which
is a table which contains the counts of reads of different reference/read categories (in total
16) and positions on the forward/reversed strand (15 positions on each direction). Table 1
528 and Table 2 give an example of the data format we use for the inference.

536 **Appendix 3—table 2.** The read counts per position given the reference nucleotides are G or T of the
 538 same human data as in Table 1. The negative position indices are the position on the reversed strand.
 540 In the manuscript, the elements (the values of a specific nucleotide read counts per position given the
 542 reference nucleotide is G or T) in this table are denoted as $o_{G \rightarrow i,p}$ or $o_{T \rightarrow i,p}$.

544 The terminology used here might not be standard. The term full regression here is to
 546 distinguish itself from the folded regression discussed later, which simply means inferring
 548 the coefficients of forward strand and reversed strand separately. Full regression includes
 550 both unconditional regression and conditional regression. The unconditional regression's
 552 objective is to infer the probability of observing a read of nucleotide j and its reference
 554 is i at position p , i.e., $P(\text{Obs} : i \rightarrow j | \text{Pos} : p)$; while the unconditional regression's target is to
 estimate the probability of observing a read of nucleotide j given its reference is i at position
 p , i.e., $P(\text{Obs} : j | \text{Ref} : i, \text{Pos} : p)$. Their relationship is as follows:

$$P(\text{Obs} : j | \text{Ref} : i, \text{Pos} : p) = \frac{P(\text{Obs} : i \rightarrow j | \text{Pos} : p)}{\sum_j P(\text{Obs} : i \rightarrow j | \text{Pos} : p)}.$$

556 So in fact, unconditional regression can give us more detailed inferred results (extra information
 558 the nucleotide composition per position of the reference, which may be related to
 560 the prepared libraries).

Unconditional Regression likelihood

$$\begin{aligned} l_1 &= \sum_p \sum_{i,j \in \{A,C,G,T\}} o_{i \rightarrow j,p} \log P_{ij|p} \\ &= \sum_p \left[o_p \log P_{TT|p} + \sum_{(i,j) \neq TT} o_{i \rightarrow j,p} \log \frac{P_{ij|p}}{P_{TT|p}} \right], \end{aligned} \quad (10)$$

562 where $P_{ij|p} = P(\text{Obs} : i \rightarrow j | \text{Pos} : p)$, and $o_p = \sum_{i,j \in \{A,C,G,T\}} o_{i \rightarrow j,p}$.

$$\log \frac{P_{ij|p}}{P_{TT|p}} = \sum_{n=0}^{\text{order}} \alpha_{i,j,p,n} p^n \quad (11)$$

$$\begin{aligned} l_1 &= \sum_p \left\{ -o_p \log \left[1 + \sum_{(i,j) \neq TT} \exp \left(\sum_{n=0}^{\text{order}} \alpha_{i,j,p,n} p^n \right) \right] + \sum_{(i,j) \neq TT} o_{i \rightarrow j,p} \sum_{n=0}^{\text{order}} \alpha_{i,j,p,n} p^n \right\} \\ &= l_{1,5'} + l_{1,3'}. \end{aligned} \quad (12)$$

568

The number of inferred parameters for the full conditional regression is 30 (order + 1).

$$\frac{\partial l_1}{\partial \alpha_{i,j,p,n}} = -o_p \frac{p^n \exp \left(\sum_{n=0}^{\text{order}} \alpha_{i,j,p,n} p^n \right)}{1 + \sum_{(i,j) \neq \text{TT}} \exp \left(\sum_{n=0}^{\text{order}} \alpha_{i,j,p,n} p^n \right)} + o_{i \rightarrow j, p} p^n. \quad (13)$$

572

Conditional Regression likelihood

$$\begin{aligned} l_2 &= \sum_{i \in \{\text{A,C,G,T}\}} \sum_p \sum_{j \in \{\text{A,C,G,T}\}} o_{i \rightarrow j, p} \log P_{j|p,i} \\ &= \sum_{i \in \{\text{A,C,G,T}\}} \sum_p \left[o_{i,p} \log P_{\text{T}|p,i} + \sum_{j \neq \text{T}} o_{i \rightarrow j, p} \log \frac{P_{j|p,i}}{P_{\text{T}|p,i}} \right], \end{aligned} \quad (14)$$

576

where $P_{j|p,i} = P(\text{Obs} : j | \text{Ref} : i, \text{Pos} : p)$, and $o_{i,p} = \sum_{j \in \{\text{A,C,G,T}\}} o_{i \rightarrow j, p}$.

578

$$\log \frac{P_{j|p,i}}{P_{\text{T}|p,i}} = \sum_{n=0}^{\text{order}} \beta_{i,j,p,n} p^n \quad (15)$$

582

$$\begin{aligned} l_2 &= \sum_{i \in \{\text{A,C,G,T}\}} \sum_p \left\{ -o_{i,p} \log \left[1 + \sum_{j \neq \text{T}} \exp \left(\sum_{n=0}^{\text{order}} \beta_{i,j,p,n} p^n \right) \right] + \sum_{j \neq \text{T}} o_{i \rightarrow j, p} \sum_{n=0}^{\text{order}} \beta_{i,j,p,n} p^n \right\} \\ &= l_{2,\text{A},5'} + l_{2,\text{C},5'} + l_{2,\text{G},5'} + l_{2,\text{T},5'} + l_{2,\text{A},3'} + l_{2,\text{C},3'} + l_{2,\text{G},3'} + l_{2,\text{T},3'}. \end{aligned} \quad (16)$$

586

The number of inferred parameters for the full unconditional regression is 24 (order + 1).

$$\frac{\partial l_2}{\partial \beta_{i,j,p,n}} = -o_{i,p} \frac{p^n \exp \left(\sum_{n=0}^{\text{order}} \beta_{i,j,p,n} p^n \right)}{1 + \sum_{j \neq \text{T}} \exp \left(\sum_{n=0}^{\text{order}} \beta_{i,j,p,n} p^n \right)} + o_{i \rightarrow j, p} p^n. \quad (17)$$

590

Folded Regression

The folded regressions use the same log-likelihood function as the full regression (i.e., Equation) but are conducted based on the assumptions that,

592

$$\alpha_{i,j,p,n} = \alpha_{c(i),c(j),-p,n}, \quad (18)$$

594

$$\beta_{i,j,p,n} = \beta_{c(i),c(j),-p,n}, \quad (19)$$

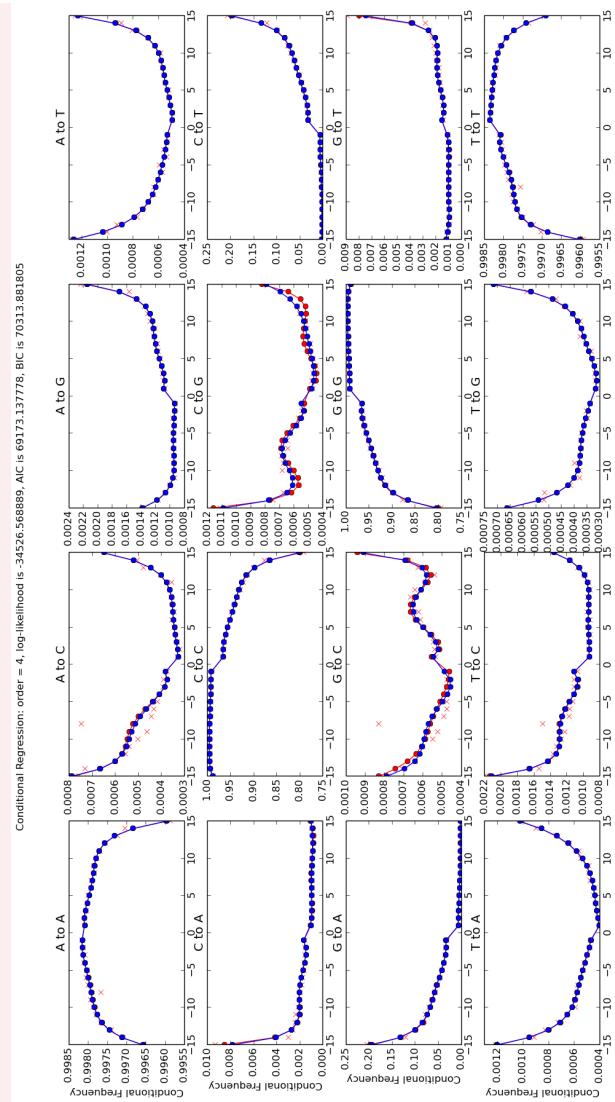

596

where $c(i)$ means the complementary nucleotide of the nucleotide i , e.g., $c(\text{A}) = \text{T}$ and $c(\text{G}) = \text{C}$. Our data (both taxon and human data) and some models studies seem to support this assumption.

598 By doing the folded regression, we halve the number of inferred parameters. Hence The
599 number of inferred parameters for the folded unconditional regression is 15 (order + 1), and
600 that of folded conditional regression is 12 (order + 1).

Results for multinomial logistic regression

602 Currently, the optimization of the likelihood functions are based on the C++ library of gsl and
603 use the function `gsl_multimin_fminimizer_nmsimplex2`. with the initial searching point is set to
604 be the results of logistic regression. We here present here 4 figures pertaining to showcase
605 the performance of our model. The regression methods are based on the summary statistic
606 of the counts of mismatches and the optimization is therefore in the scale of miliseconds.
607 Fig. 1 and Fig. 2 are the conditional regression results of the ancient and control human
608 data correspondingly. And Fig. 3 and Fig. 4 are the folded conditional regression results of
609 the same data as above. Our codes can also do the unconditional regression, but I have not
610 generated the results for now.

Dear Dr. Kharasch

Enclosed is our manuscript entitled: "Preoperative prediction of medical morbidity after fast-track hip and knee arthroplasty - a machine learning based approach." This study investigates potential advantages of a state of the art machine-learning model comprising 33 preoperative variables and including novel use of preoperative dispensed prescriptions within 3 months preoperatively, for prediction of postoperative medical complications resulting in prolonged hospitalizations or readmissions in fully implemented fast-track total hip and knee replacement. We believe that our results are an important contribution within the field of perioperative medicine and risk-prediction, especially the novel analyzes on the specific contributions of individual risk-factors in the machine-learning model. Consequently, we hope you will consider our study for publication in Anesthesiology.

We are aware of the large number of figures, most of which are Supplemental Digital Content. However, due to difficulties in combining the 4 panels of Figure 3a-d into a single PDF-file these have been submitted as separate files. We hope that you are able to assist in combining these panels into a single figure during the editorial process in case of acceptance.

Kind regards, on behalf of the authors
Christoffer Jørgensen and Henrik Kehlet

Abstract

Background: Introduction of machine-learning models has potentially improved prediction of postoperative hospitalization and morbidity after hip and knee replacement. However, few studies include enhanced recovery programs, and most rely on administrative coding with limited follow-up and information on perioperative care. Thus, benefits of machine-learning models for prediction of postoperative morbidity in enhanced recovery hip and knee replacement remain uncertain.

Methods: Multicenter cohort study from 2014-2017 in enhanced recovery total hip and knee replacement. Prospective recording of comorbidity and prescriptions. Information on length of stay and readmissions through the Danish National Patient Registry and medical records. Data was split into training (n:18013) and test sets (n:3913). A machine-learning model with 33 variables was used for predicting “medical” morbidity with a length of stay of >4 days or 90-days readmission and compared to a full logistic regression model. In addition, a machine-learning model excluding age, an age-only model and parsimonious machine-learning and logistic regression models using the ten most important variables were evaluated. Model performances were evaluated using several metrics, including precision, operating receiver (AUC) and precision recall curves (AUPRC). Variable importance was analyzed using Shapley Additive Explanations values.

Results: With 782 (20%) “risk-patients”, precision, AUC and AUPRC were 13.6%, 76.3% and 15.5% for the full and 12.8%, 75.9% and 17.1% for the parsimonious machine-learning models vs. 12.5%, 74.5% and 15.7% for the full logistic regression model. The machine-learning model excluding age and the Age-only model performed worse. Of the top ten variables, eight were shared between the full machine-learning and logistic regression models, and the importance of specific prescribed drugs varied considerably with age.

Conclusion: A machine-learning algorithm using preoperative characteristics and prescriptions likely improves identification of patients in high-risk of medical complications after fast-track hip and knee replacement. Such algorithms could help identify patients who benefit from intensified perioperative care.

INTRODUCTION

Prediction of postoperative morbidity and requirement for hospitalization is important for planning of health care resources. With regard to the common surgical procedures of primary total hip and knee arthroplasty, the introduction of enhanced recovery or fast-track programs has led to a significant reduction of postoperative length of stay (length of stay) as well as morbidity and mortality.¹⁻³ However, despite such progress, a fraction of patients still have postoperative complications leading to prolonged length of stay or readmissions.^{1,3,4}

Consequently, in order to prioritize perioperative care, many efforts have been published to preoperatively predict length of stay and morbidity using traditional risk factors such as age, preoperative cardio-pulmonary disease, anemia, diabetes, frailty, etc.⁴⁻⁸ These efforts have been based on traditional statistical methods, most often multiple regression analyses, and essentially concluding that it is “better to be young and healthy than old and sick”.

Consequently, despite being statistically significant, conventional risk-stratification based on such studies has had a relatively limited clinically relevant ability to predict and reduce potentially preventable morbidity and length of stay.⁴⁻⁸

More recently, machine-learning methods have been introduced with success in several areas of healthcare and where preliminary data suggest them to improve surgical risk prediction compared to traditional risk calculation in certain anesthetic and surgical conditions.^{9,10} This is also the case in total hip replacement, total knee replacement and uni-compartmental knee replacement, where several publications on machine-learning algorithms for prediction of length of stay,^{11,12} complications,¹³ disability,¹⁴ potential outpatient setup,¹⁵ readmissions¹⁶ or payment models,^{17,18} have shown promising predictive value compared to conventional statistical methods.¹⁹

However, few papers have included enhanced recovery programs, and most are based on large database cohorts with the presence of risk factors and complications often relying on administrative coding with limited information on perioperative care, follow-up and discharge destination. In our previous study of 9512 total hip and knee replacements within an enhanced recovery protocol and including the above information, we did not find advantages of machine-learning methods compared to logistic regression in predicting a length of stay > 2 days.²⁰ However, this may have been due to data imbalance, lack of details on medication and the chosen outcome of length of stay of >2 days.²⁰ Thus, machine-learning models remain promising and could provide an improved basis for identifying a potential “high-risk” surgical

1
2
3
4 population who may benefit from more extensive preoperative evaluation and postoperative
5 medical care.
6

7 Consequently, we analyzed whether an improved machine-learning model was better for
8 preoperative prediction of medical complications resulting in prolonged length of stay and
9 readmissions compared to a traditional logistic regression model, in a large consecutive cohort
10 of patients undergoing fast-track total hip and knee replacement within a national public health-
11 care system.¹ In addition to well-defined patient-reported preoperative risk-factors, we also
12 included information on dispensed reimbursed prescriptions 6 months prior to surgery using a
13 nationwide registry.²¹

19 Reporting of the study is done in accordance with the Transparent reporting of multivariable
20 prediction model for individual prognosis or diagnosis (TRIPOD) statement²² and the Clinical AI
21 Research (CAIR) checklist proposal.²³
22

23 The study is based on the Centre for Fast-track Hip and Knee Replacement database which is a
24 prospective database on preoperative patient characteristics and enrolling consecutive patients
25 from 7 departments between 2010 and 2017. The database is registered on ClinicalTrials.gov
26 as a study registry (NCT01515670). Permission to review and store information from medical
27 records without informed consent was acquired from Center for Regional Development (R-
28 20073405) and the Danish Data Protection Agency (RH-2007-30-0623). Patients completed a
29 preoperative questionnaire with nurse assistance if needed. Additional information on
30 reimbursed prescriptions 6 months prior to surgery was acquired using the Danish National
31 Database of Reimbursed Prescriptions (DNDRP) which records all dispensed prescriptions with
32 reimbursement in Denmark.²¹ Finally, data were combined with the Danish National Patient
33 Registry (DNPR) for information on length of stay (counted as postoperative nights spent in
34 hospital), 90-days readmissions with overnight stay and mortality. In case of length of stay >4
35 days or readmission, patient discharge summaries were reviewed for information on
36 postoperative morbidity and in case of insufficient information, the entire medical records were
37 reviewed. Readmissions were only included if considered related to the surgical procedure, thus
38 excluding planned procedures like cancer workouts, cataract surgery, etc. Readmissions due to
39 urinary tract infection or dizziness after day 30 were also considered unrelated to the surgical
40 procedure. In case of postoperative mortality the entire medical record, including potential

readmissions, was reviewed to identify cause of death. Evaluation of discharge and medical records was performed by PP supervised by CJ. In case of disagreement, records were conferred with HK. Subsequently, causes of length of stay >4, readmissions or mortality were classified as “medical” when related to perioperative care (renal failure, falls, pain, thrombosis, anemia, venous thromboembolism or infection etc.) and “surgical” if related to surgical technique (prosthetic infection, revision surgery, periprosthetic fracture, hip dislocation, etc.).¹ In case of a length of stay 4-6 days with a standard discharge summary describing a successful postoperative course, it was assumed that no clinically relevant postoperative complications had occurred. If length of stay was >6 days but with standard discharge summary, the entire medical record was evaluated to confirm that no relevant complications had occurred.

For the present study, only cases between 2014 and 2017 were used to provide the most up-to date data. All patients had elective unilateral total hip and knee replacement in dedicated arthroplasty departments with similar fast-track protocols, including multimodal opioid sparing analgesia with high-dose (125mg) methylprednisolone, preference for spinal anesthesia, only in-hospital thromboprophylaxis when length of stay ≤5 days, early mobilization, functional discharge criteria and discharge to own home.¹ There was no selection criteria for the fast-track protocol as it is considered standard of care, but we excluded patients with previous major hip or knee surgery within 90-days of their total hip or total knee replacement and total hip replacement due to severe congenital joint disorder or cancer.

Outcomes

The primary outcome was to compare prediction quality when using a machine-learning model to predict the occurrence of “medical” complications resulting in a length of stay >4 days or readmission compared to a traditional logistic regression model (outcome A). Secondarily, we investigated how inclusion of cases with a length of stay >4 days but no reported “medical” complication as a positive outcome influenced the model (outcome B). For both outcomes, we also investigated whether a parsimonious model including only the top ten variables would perform equally well as the full model, and whether the effect of age per se would compare to the full machine-learning model. All figures and tables in the main text and Appendix are based on outcome A; the corresponding figures for outcome B are reported in the Supplemental Digital Content.

Statistical Analysis

Data was initially trimmed by removing 156 patients (1.7%) who were outliers with regards to weight (<30 kg or >250 kg) and height (<100 cm or >210 cm) or where these data were missing. To reduce the risk of overfitting, the dataset was subsequently split into a training set consisting of 18.013 (82.2%) procedures from 2014-2016 and a test set of 3913 (17.8%) procedures from 2017.

As a reference model, we used classical logistic regression using all 33 input variables (table 1). Cases of missing values in the logistic regression model were handled by imputing missing values with the median of present values. All variables were then normalized.

In addition, we used Boosted Decision Trees (LightGBM)²⁴ for the machine-learning models, as such methods work well with categorical data and missing values. We tried using both normal cross entropy and FocalLoss²⁵ as the objective function for the machine-learning model. The reason for testing FocalLoss was to allow the machine-learning model to focus more on the (few) positives.

The full machine-learning model was trained and hyperparameter optimized using state of the art machine-learning methods. The models were trained on the training data and then used for making predictions on the unseen test data (see supplementary for details). The classification threshold was calibrated such that no more than 20% of the total number of patients were predicted as positive by the model (a positive predictive fraction (PPF) of 20%). We also included results for PPF values of 25% and 30%. Furthermore, we trained two parsimonious models using machine-learning and logistic regression with only the 10 most important features. Finally, we specifically explored the influence of increasing age, by constructing a model based only on age (Age), and a machine-learning model based on all variables except for age.

To investigate the importance of the included variables, we computed the SHapley Additive exPlanations (SHAP) values, which provide estimates on which variables contribute most to the risk score predictions.^{26,27} Finally, we investigated a potential relation between reimbursed prescribed cardiac drugs, anticoagulants, psychotropics and pulmonary drugs and age, as the relation between polypharmacy and postoperative outcomes have mainly been found in older patients.²⁸

For evaluating model performance, we computed the number of true positives, false positives, false negatives, true negatives, sensitivity (true positive rate), precision (positive predictive value). Since the data was quite imbalanced (about a 1:20 positive:negative ratio) we also computed the Matthews Correlation Coefficient (MCC) which is independent of class

imbalance.^{29,30} The MCC ranges between -1 (the 100% wrong classifier), 0 (the random classifier), and +1 (the perfect classifier). Finally, we computed the area under the receiver operating characteristic curve (AUC) and the area under the precision recall curve (AUPRC). To evaluate the statistical difference between the classifiers, we applied a Bayesian metric comparison $P(\text{sensitivity})$,³¹ which is the probability that a model will perform better than the machine-learning model relative to the sensitivity. Thus, for two equally performing models $P(\text{sensitivity})$ is $\approx 50\%$.

Results

Median age in the 3913 patients was 70 years (IQR 62-76), 59% were female and 58% had total hip replacement (table 1). Details on prescribed drug types are shown in Appendix 1. Median length of stay was 2 (IQR: 1-2) days with 7.6% 90-days readmissions and outcome A occurring in 182 (4.7%) patients. When applying any model with a positive prediction fraction of 20% to the 3913 patients, 782 qualified as “risk-patients”. The results are summarized in figure 1 and table 2. When considering risk scores from the full machine-learning (figure 1a) and full logistic regression model leading to this risk-patient selection, 106 and 98 had outcome A, respectively. Correspondingly, the sensitivity and precision were 58.2% and 13.6% for the full machine-learning and 53.8% and 12.5% for the full logistic regression model, respectively. The full machine-learning model was superior (figure 1b) on essentially all parameters compared to any of the other models, although the differences were minor (table 2). The results were similar when using positive prediction fractions of 25% and 30%, but with the sensitivity for the full machine-learning model increasing to 64.4% and 69.2% and precision decreasing to 12.0% and 10.7%, respectively (Appendix table 2).

Both the machine-learning model excluding age and age-only model had significantly lower sensitivity than the full machine-learning model (figure 1b). Despite age being the single most important variable (figure 2), the machine-learning model excluding age performed as well as the age-only model.

When evaluating feature importance, we found a strong correlation between the full machine-learning and full logistic regression model, with age and use of walking aids being the most important variables in both (figure 2a). From the combined importance of variables outside the top ten, the machine-learning approach extracted more information with fewer variables than logistic regression (figure 1b).

1
2
3
4 For the full machine-learning model, there was a clear signal that increasing age, number of
5 reimbursed prescriptions, and presence of comorbidity, all contributed to an increased risk
6 score. In contrast, a recent date of surgery and an increased hemoglobin level seemed to
7 reduce the calculated risk (figure 2b). Individual analysis of the SHAP interaction values for
8 types of anticoagulant prescriptions revealed that prescriptions on vitamin-K antagonists (VKA)
9 or adenosine diphosphate (ADP) antagonists increased, while acetylic salicylic acid and direct
10 oral anticoagulants (DOAC) reduced the risk score of the full machine-learning model,
11 regardless of age (figure 3a). The SHAP analysis of prescribed cardiac drugs revealed that
12 prescriptions on Ca^{2+} -antagonists and betablockers in combination with one or two other
13 antihypertensives increased the risk-score, as did prescriptions on nitrates, other
14 antihypertensives and antiarrhythmics. For the remaining cardiac drugs, prescriptions either
15 reduced or had minor influence, and with limited relation with age (figure 3b). Preoperative
16 psychotropic prescriptions increased the risk-score except for antipsychotics (0.6%). For users
17 of selective serotonin inhibitors there was a clear age-related distinction with the risk score
18 being increased in elderly patients but decreased in those < 60 years (figure 3c). Finally, the risk
19 score increased with prescriptions on inhalation steroid and β -blockers, and more accentuated
20 in the younger patients (figure 3d).

21
22
23
24 The results including patients with a length of stay >4 days, but no reported postoperative
25 complications (outcome B) were similar as for outcome A. In general, we found that the full
26 machine-learning model was superior to the others, although the difference were smaller than
27 for outcome A. (Supplemental Digital Content table S1 listing outcome parameters and
28 Supplemental Digital Content 2 figure S1a-b showing distributions and ROC curves for outcome
29 B). While the ten most important variables for the full machine-learning model remained
30 unchanged, familiar disposition for venous thromboembolism replaced gender as one of the top
31 ten important variables in the full logistic regression model (Supplemental Digital Content figure
32 S2a-b showing SHAP values for outcome B). Furthermore, the SHAP analysis on specific
33 prescribed drugs demonstrated that the machine-learning model found no benefits from
34 information on prescriptions on respiratory drugs, why all SHAP values were zero. In addition,
35 the reduced risk with acetylsalicylic acid and DOAC prescriptions, as well as the influence of
36 practically all cardiac drugs except for nitrates, other antihypertensives and antiarrhythmics, was
37 attenuated (Supplemental Digital Content 4 figure S3a-d showing SHAP-values of prescriptions
38 of specific drugs for outcome B).

Discussion

We found that using a machine-learning algorithm including all 33 available variables and a parsimonious machine-learning-algorithm encompassing only the 10 most important predictors improved prediction of patients at increased risk of having a length of stay >4 days or readmissions due to medical complications compared to traditional logistic regression models. In contrast, when also including patients having a length of stay >4 days but without a well-defined complication as an outcome, the parsimonious machine-learning model was slightly worse than a traditional logistic regression model including all variables. We also found that although age was the single most important predictor of both outcome A and B, it was less suited for prediction of postoperative medical complications after fast-track total hip and knee replacement on its own. Finally, we demonstrated how the chosen classification threshold of the machine-learning algorithm influenced model performance through an increase in sensitivity at the cost of decreased precision.

A previous systematic review also found that machine-learning algorithms may provide better prediction of postoperative outcomes in THA and TKA.³² However, the authors concluded that such models performed best at predicting postoperative complications, pain and patient reported outcomes and were less accurate at predicting readmissions and reoperations.³² That machine-learning algorithms may improve prediction of complications after THA and TKA compared to traditional logistic regression was also found by Shah *et al.* who used an automated machine-learning framework to predict selected major complications after THA.¹³ However, theirs was a retrospective study based on diagnostic and administrative coding and the selected complications occurred only in 0.61% of patients, potentially limiting clinical relevance. In contrast, we aimed at identifying a cohort which would comprise 20% of patients in which we found about 60% of all medical complications. This we believe, is within the means of the Danish socialized healthcare system to allocate additional resources for intensified perioperative care and with both patient-related and economic benefits due to potentially avoided complications and costs.

In contrast to many other machine-learning studies,³³ our dataset included not only preoperative data but also only one paraclinical variable, which was preoperative hemoglobin. Although the inclusion of other laboratory tests such as preoperative albumin, sodium and alkaline phosphatase has been found to be of importance in machine-learning algorithms for home discharge in UKA¹² and spine surgery,⁹ they are not standard in our fast-track protocols and not easy to interpret from a pathophysiological point of view. As there is a need to prioritize the

1
2
3
4 limited health-care resources, most decisions on which patients may benefit from more
5 extensive postoperative care will likely need to be conducted preoperatively. Thus, although
6 postoperative information such as duration of surgery, perioperative blood length of stays or
7 postoperative hemoglobin have been included in other studies³³, we decided against the use of
8 peri- and postoperative data. The same approach has been used by Ramkumar *et al.* who used
9 U.S. National Inpatient Sample data including 15 preoperative variables, to predict length of
10 stay, patient charges and disposition after both TKA³⁴ and THA.¹⁸ However, these studies were
11 not conducted in a socialized health care system, and the main focus was on the need for
12 differentiated payment bundles and without specific information on the reason for increased
13 length of stay or non-home discharge.³⁴ Wei *et al.* used an artificial neural network model to
14 predict same-day discharge after TKA, based on the NSQUIP database from 2018 and found
15 that six of the ten most important variables were the same compared with logistic regression,
16 similar to our findings.³⁵ However, patients with one-day length of stay were intentionally
17 excluded due to variations in in-patient vs. out-patient registration.³⁵

18 Age has traditionally been a major factor when predicting surgical outcomes which is why we
19 choose to specifically evaluate its effect on our risk-prediction. That age is important for risk-
20 prediction was further illustrated by the machine-learning model without age being comparable
21 to the age-only model. Note that, although elderly patients had increased risk of postoperative
22 complications, likely related to decline of physical reserves,³⁶ the use of chronological age alone
23 as a selection criteria for being a “risk-patient” was inferior compared to both machine-learning
24 and logistic regression models incorporating comorbidity and functional status.

25 We used the SHAP values for estimation of feature importance, thus providing a better
26 understanding of the otherwise “black-box” machine-learning model. The SHAP values showed
27 which variables contribute most to the risk-score predictions.

28 Our inclusion of specific data on reimbursed prescriptions 6 months prior to surgery based upon
29 the unique Danish registries, unsurprisingly found increased risk-scores with increased number
30 of prescriptions and with the majority being in elderly patients. Similarly, a Canadian study in
31 elective non-cardiac surgery found decreased survival and increased length of stay and
32 readmissions and costs in patients >65 years with polypharmacy.²⁸ However, this is a complex
33 relationship where some patients benefit from their treatments, while other may suffer from
34 undesirable side-effects. Consequently, the authors cautioned against altering perioperative
35 practices based on current evidence.²⁸ However, the information from the included prescriptions
36 with SHAP analysis may provide inspiration for new hypothesis-generating studies such as
37 investigation of the potential differences in risk-profile between having preoperative prescribed
38

VKA and DOAKs. Also, the age-related differences in risk from SSRI's seen in our study could guide further studies on "deprescription".

Another requirement for machine-learning-algorithms to be clinically useful is user friendliness and not depending on excessive additional data collection by the attending clinicians. In this context, it was a bit disappointing that the parsimonious machine-learning algorithm with only the ten most important variables was slightly worse at predicting outcome B than the full logistic regression model. A reason for this could be that when including a length of stay >4 days but without described medical complications, the combination of all variables provide information not available by merely including the ten most important ones. This highlights the need for as much detailed, and preferably non-binary, data as possible to fulfill the true potential of machine-learning algorithms.

Our study has some limitations. First, one of the strengths of machine learning compared to logistic regression is the analysis of multilevel continuous data, whereas we included only a limited number of, often binary, preoperative variables. This could have limited the full realization of our machine learning model. As previously mentioned, we excluded intraoperative information, including type of anesthesia, surgical approach etc. all of which may influence postoperative outcomes. The observational design of this study means that we cannot exclude unmeasured confounding or confounding by indication. Also, despite that the DNDRP has a near complete registration of dispensed medicine in Denmark, some types or drugs, especially benzodiazepines, are exempt from general reimbursement and thus not sufficiently captured.²¹ Furthermore, it is doubtful whether the patients used all types of drugs at the time of surgery (e.g. heparin which is rarely for long-term use). Finally, classification of a complication being "medical" depended on review of the discharge records which can also introduce bias. However, we believe our approach to be superior to depending only on diagnostic codes which often are inaccurate³⁷ and provide limited details on whether the complication may be attributed to a medical or surgical adverse event. The strengths of our study include the use of national registries with high degree of completion (>99% of all somatic admissions in case of the DNDRP),³⁸ prospective recording of comorbidity, extensive information on prescription patterns 6 months prior to surgery and similar established enhanced recovery protocols in all departments.

In summary, our results suggest that machine-learning-algorithms likely provide clinically relevant improved predictions for defining patients in high-risk of medical complications after fast-track THA and TKA compared to a logistic regression model. Future studies could benefit

from using such algorithms to find a manageable population of patients who benefit from intensified perioperative care.

Figure legends

Figure 1a-b

1a) Distribution of full machine learning model risk scores for patients +/- outcome A. The dashed line marks the classification threshold of 20% positive prediction fraction.
1b) Receiver operating curves (ROC) for the full machine learning model (F-MLM), full logistic regression model (F-LRM), parsimonious machine learning model (P-MLM), parsimonious logistic regression model (P-LRM), machine learning excluding age (MLM -age) and the age-only model (AM).

Figure 2a-b

2a) The overall importance of the 10 most important variables measured by the SHAP-values for the full machine-learning and full logistic regression models on outcome A (LOS >4 days or readmission due to “medical” morbidity). Only the importance of prescribed anticholesterols and gender differ between the models. The contributions of the remaining variables are summed in the bottom bar.
2b) The SHAP-values for the full machine-learning model on outcome A, where positive increase and negative values decrease the risk score. The color is related to the value of the variable with blue being lowest and red highest and each dot represents a patient.

Figure 3a-d

SHAP scatter-plot on the contributions to the full machine-learning model on outcome A (LOS >4 days or readmission due to “medical” morbidity), for individual types of prescribed anticoagulants, cardiac drugs, psychotropics and respiratory drugs stratified by age.

3a) Prescribed anticoagulants

VKA: vitamin K antagonists ASA: acetylsalicylic acid DOAC: direct oral anticoagulant ADP: Adenosine diphosphate ACE: angiotensin converting enzyme

3b) Prescribed cardiac drugs

ACE: angiotensin converting enzyme AHT: antihypertensive. Other AHT were defined as AHT different from diuretics ANG-II/ACE inhibitors or Ca²⁺antagonists. IHD: Ischemic heart disease

3c) Prescribed psychotropics

SSRI: Selective serotonin inhibitor SNRI: Serotonin and norepinephrine reuptake inhibitor NaRI: Norepinephrine reuptake inhibitor NASSA: Norepinephrine and specific serotonergic antidepressants. AD: antidepressants BZ: Benzodiazepines (likely underreported due to limited general reimbursement in Denmark). ADHD: Attention-deficit/hyperactivity disorder

3d) Prescribed respiratory drugs

SABA: Short-acting beta agonist LABA: long-acting beta agonist LAMA: Long-acting muscarinic antagonist.

Table 1. patient demographics with and without outcome A (length of stay >4 days or readmissions due to "medical" morbidity) in the combined test and training dataset.

Preoperative characteristics n (%) unless otherwise specified	+outcome A (n:1180)	-outcome A (n:20837)

The modelling of pandemics has become a critical aspect in modern society. Even though artificial intelligence can help the forecast, the implementation of ordinary differential equations which estimate the time development in the number of susceptible, (exposed), infected and recovered (SIR/SEIR) individuals is still important in order to understand the stage of the pandemic. These models are based on simplified assumptions which constitute approximations, but to what extent this are erroneous is not understood since many factors can affect the development. In this paper, we introduce an agent-based model including spatial clustering and heterogeneities in connectivity and infection strength. Based on Danish population data, we estimate how this impacts the early prediction of a pandemic and compare this to the long-term development. Our results show that early phase SEIR model predictions overestimate the peak number of infected and the equilibrium level by at least a factor of two. These results are robust to variations of parameters influencing connection distances and independent of the distribution of infection rates.

1. Introduction

Over the past years, the pathogen now known as SARS-CoV-2 has spread dramatically, risen in several waves, paralyzing societies, resulting in a large number of deaths and severe economic damage worldwide [1,2]. Mathematical models have estimated the reproduction number and guided the authorities in an attempt to minimize the damage caused by the virus [3–6]. Even though modern algorithms using machine learning have helped the process [7,8], the majority of models used to predict the size of the pandemic (or a rising wave of the disease) have been variants of the SIR/SEIR model. The SIR model was originally proposed in 1927, in the seminal work of Kermack and McKendrick, who successfully described the evolution of a pandemic, using a mean field approximation where all individuals are described as one population [9]. In the investigations of the SARS-CoV-2 pandemic, the mathematical models have varied in complexity including simple deterministic compartmental models [6,10], meta-population compartmental models [11–13], individual based models without including spatial specifications [4,14,15] and spatio-temporal agent-based models [16].

One aspect in the modelling is the ability to predict the infection peak height and the number of individuals who will be infected based on the early rise in the number of infected (before governmental interference). Earlier work has pointed out the importance of including heterogeneity when modelling the spread of infectious disease such as contact patterns between individuals [17], population mixing assumptions [18], heterogeneities caused by super-spreaders [15], and the spatial dependency of COVID-19 [19,20]. These mathematical models have not combined heterogeneous elements nor quantified how much the early SIR/SEIR predictions might be biased.

In this paper, we include geographical distributions based on an entire population, using population data of Denmark. When the SIR model was originally formulated, 95 years ago, data was not available to investigate the effects of geographical and demographic differences among the population, which might be one of the reasons why fundamental properties for diseases, such as the basic reproduction number (R_0), can vary significantly between different regions [21]. However, with modern collection of data, these geographical aspects might be accounted for. Our main goal of this work is therefore to investigate the importance of heterogeneities in a geographically distributed population on the spread of a pandemic. We find that the heterogeneity arising from spatial inhomogeneities causes an increase in the early stage of the pandemic, affecting the initial forecast and highlighting the importance of early intervention in order to minimize the effects of the pandemic.

1.1. Construction of the model

In order to investigate the effect of a geographically distributed population, we extracted the number of infected per commune (from the Danish Serum Institute [22]) and divided this number with the number of inhabitants in each commune to obtain the number of infected per individual in each commune. This number we then plotted against the number of inhabitants in that specific commune (extracted from statistics Denmark [23]). Doing so, we found a strong correlation between the population density and the number of infections per inhabitant as seen in figure 1a. This observation has been made for many other countries [24–29] and underlines the aspect of disease spreading that has been observed since ancient times; that densely populated regions often have larger pandemics than the rural areas. Note that in the very early stage of a pandemic, before the exponential growth rate is reached, micro outbreaks will guide its evolution and these events can likely take place in regions with low density [30].

1.2. Disease simulation

To simulate evolution of the disease, we assigned each individual (agent) to a state (predominantly initialized in state S) and assigned four states to the exposed phase and four states to the infectious phase, in order to achieve an Erlang distribution (which is related to the Gamma distribution) of time in each phase [31]. Once in the exposed phase, the infected agent has a rate to move into another state, where the rate is fixed based on experimental data in order to achieve a mean time in the exposed phase of approximately 4 days (table 1). Each agent in the Infectious phase can infect other agents that have a connection to this agent in the network. This definition of agents in discrete states is naturally a simplification of the real pandemic, and we stress that this mathematical model aims at describing the spread of the disease in a simple way that does not capture all aspects of the real disease. We do not believe that this impacts our main conclusions in any way, as we are aware that one should always be careful when making these kinds of simplifications. To investigate the effect of

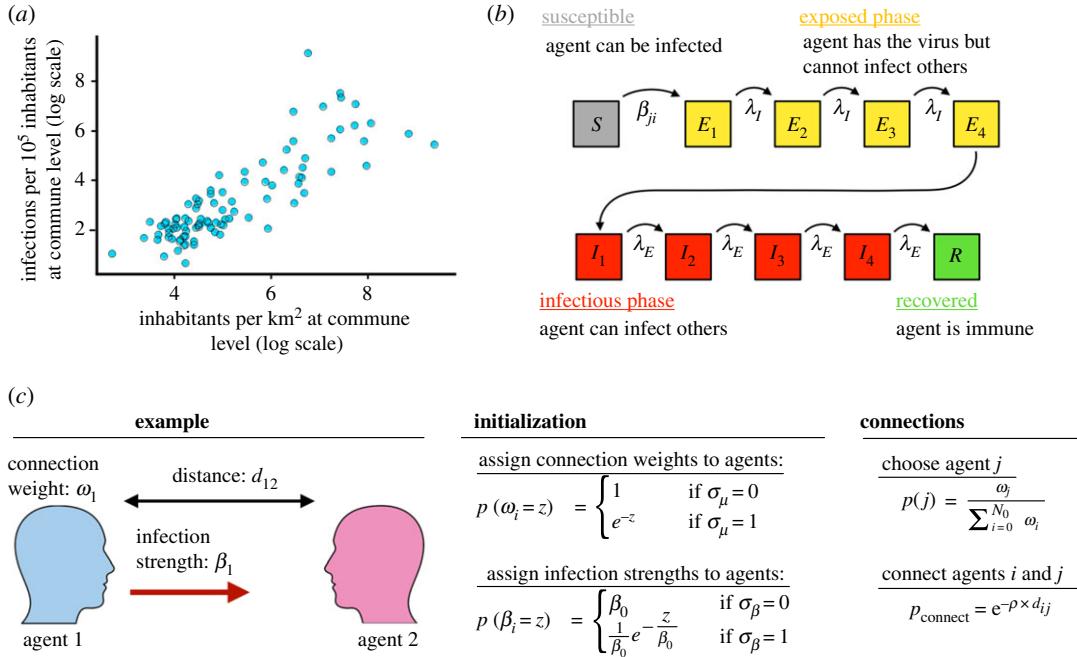

Figure 1. (a) Population density (x -axis) and the number of infections per 10^5 inhabitants (y -axis) for each commune in Denmark. (b) Illustration of the modified susceptible-exposed-infected-removed (SEIR) model used. It consists of 10 consecutive states (S, E_{1-4}, I_{1-4} and R), with transition rates governed by β, λ_E and λ_I , respectively. (c) Illustration of how the spatial network is generated and heterogeneities in individuals included.

infection heterogeneities, we assigned an infection strength to each connection in the network, so some agents were more infectious than others. In order to control the degree of this heterogeneity, we assigned a boolean parameter σ_β , that if switched on generated an exponential distribution in infection strengths, keeping the mean field reproduction number fixed. The reproduction number between the ABM and the SIR model is related through the parameter $\tilde{\beta} = \beta(\mu/2N_0)$. All transitions between states and infection of other individuals were done using the Gillespie algorithm [32]. This is schematized in figure 1b.

1.3. Network creation

In order to construct the underlying network, we created a set-up whereby two agents were chosen at random but based on their individual connectivity weight each iteration and connected with some probability based on their spatial position. To include the possibility of highly connected individuals independent of their spatial position, we assigned a boolean parameter σ_μ that, if switched on, generated an exponential distribution in weights for the individuals, keeping the mean field reproduction number fixed similar to the heterogeneity in infection strengths. To include the spatial position in the network, we introduced a parameter ρ , so the probability of connecting two chosen agents decayed exponentially with the distance between them: $p_{\text{connect}} = e^{-\rho \times d_{ij}}$. In order to allow some long-distance connections we introduced another parameter $\epsilon \in [0; 1]$, that determines the fraction of distance-independent contacts. To construct the network of spatially distributed contacts, we chose the parameters using data based on:

- The geographical location of people in Denmark (from Boligsiden [33])
- The average number of contacts per individual per day of 11 (from HOPE [34]). Given an average infectious period of 4 days, we approximate the average number of effective contacts to be $\mu = 40$
- The average commuting distance $\rho = 0.1 \text{ km}^{-1}$ and the fraction of long-distance commutes $\epsilon_\rho = 4\%$ (from statistics Denmark [23])

This is schematized in figure 1c and further described in the Methods section. All 10 parameters in this model are defined and outlined in table 1. We note that in order to keep the parameters space low, this model does not include the effects of temporal changes such as seasonality and holidays. While all agents

Table 1. Overview of the 10 parameters applied in this study, their typical value, and the ranges we have considered. The first six parameters are standard SEIR parameters, whereas the last four parameters define the heterogeneity in the model. These four parameters do not affect the SEIR model.

variable	description	value	range	units
N_0 :	population size	5.8×10^6	$10^5 - 10^7$	—
N_{init} :	number of individuals initially infected	100	$1 - 10^4$	—
μ :	average number of network contacts	40	$10 - 100$	—
β :	typical infection strength	0.01	0.001–0.1	d^{-1}
λ_F :	rate to move through $\frac{1}{4}$ of latency period	1	0.5–4	d^{-1}
λ_I :	rate to move through $\frac{1}{4}$ of infectious period	1	0.5–4	d^{-1}
σ_μ :	population clustering spread	0	0–1	—
σ_β :	interaction strength spread	0	0–1	—
ρ :	typical acceptance distance	0.1	0–0.5	km^{-1}
ϵ_ρ :	fraction of distance-independent contacts	0.04	0–1	—

have been assigned parameters to their infection network that are derived from statistics of Denmark for both employees and students, we have not divided each agent into specific occupations.

Before including heterogeneity, we compared the ABM to the corresponding SEIR model as a test, and found them to agree within 5% for all parameter configurations tested. Here, we also tested the effect of the number of individuals initially infected (see electronic supplementary material). This concludes that the SEIR and ABM model are calibrated to have the same reproduction number in the absence of heterogeneities. Next, we will introduce heterogeneities into the system, while keeping the sum of contacts and infection strengths constant, to study how this affects the evolution of the pandemic.

2. Results

2.1. Geographical distributions in a population and large variances in numbers of contacts leads to increased infection levels

Having introduced heterogeneity, the distributions of connections in this network were created automatically through the population clustering, see figure 2a. This naturally leads to individuals living in densely populated areas having higher number of connections. In an example simulation with 100 initially infected individuals, $N_{\text{init}} = 100$, we observed a spatial difference in areas affected by the disease (figure 2b), as expected. Note that we also show the effective reproduction number (\mathcal{R}_{eff}) as a function of time in the lower part of the inserted panel. One region reached local endemic steady state (green arrow, figure 2b) while other regions of similar density were highly infected (red arrow, figure 2b) and yet other districts were almost unaffected (grey arrow, figure 2b). To quantify the effect of population clustering, we compared the ABM result to the reference SEIR model of similar parameters. Generally, we observed that the epidemic developed faster with a higher infection peak I_{peak} , but also subsided quicker, leading to a lower number of infected once reaching endemic steady state, R_∞ (figure 2c,d).

In order to explore how population clustering affects the epidemic, we chose a reference value of infection rates, $\beta = 0.01$, and an alternative value of $\beta = 0.007$. In the absence of spatial dependence ($\rho = 0 \text{ km}^{-1}$), these correspond to initial reproduction numbers $\mathcal{R}_0 \approx 1.7$ and 1.1, respectively. Here, we define the reproduction number as the average number of agents each infectious agent will infect in the first part of the disease. Increasing the spatial dependence (i.e. increasing ρ) leads to a significant rise in the infection peak for the ABM, $I_{\text{peak}}^{\text{ABM}}$, compared to the (unaffected) SEIR model, $I_{\text{peak}}^{\text{SEIR}}$ for both the reference value and the alternative lower value of β (black and blue points, figure 2e). We introduced heterogeneity in infection strengths ($\sigma_\beta = 1$, see figure 1b), thus making some individuals much more infectious than others (i.e. including *super shedders*). We found no significant impact from this effect (red points in figure 2e). Similarly, we introduced heterogeneity in connection weights ($\sigma_\mu = 1$, see figure 1b), thus making some individuals much more likely to form contacts than others

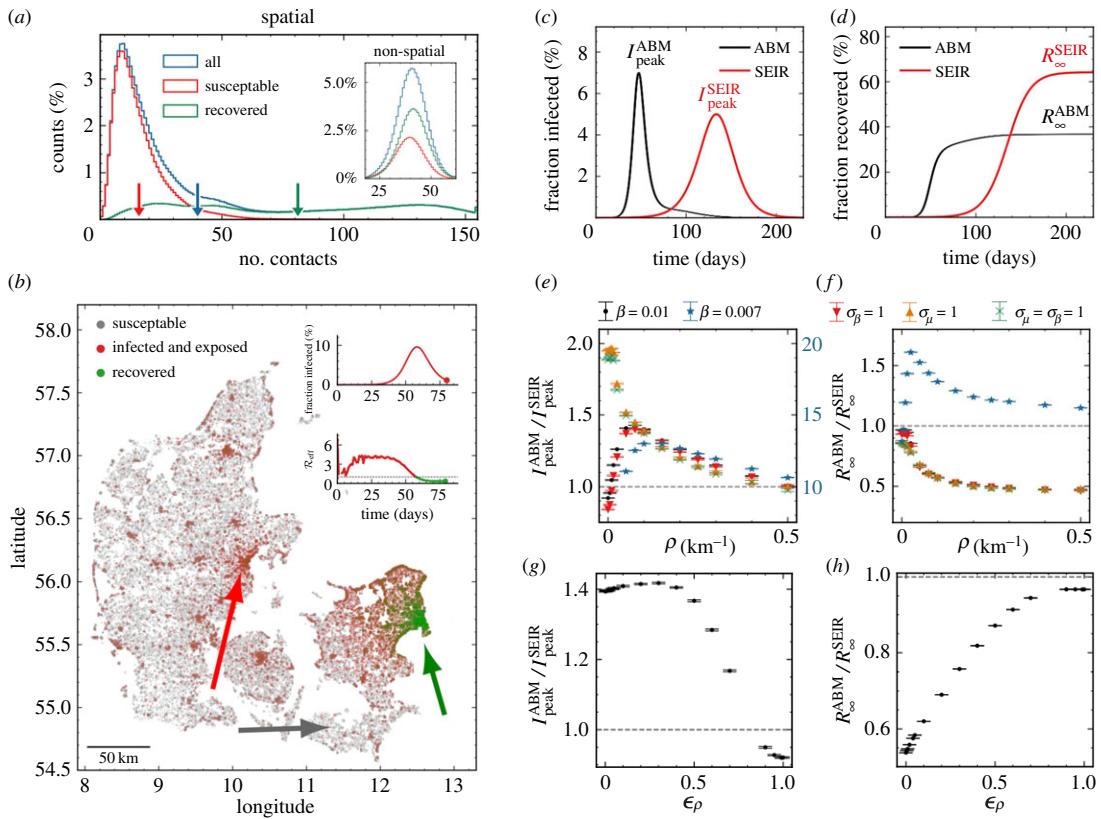

Figure 2. (a) Histograms showing the number of susceptible (red) and recovered (green) individuals at the end of an epidemic with $\rho = 0.1 \text{ km}^{-1}$. The distribution before the epidemic is shown in blue. The arrows show the mean of each distribution. The inset shows the same for $\rho = 0 \text{ km}^{-1}$. (b) Visualization of the spatial position of individuals during the infection and which state they are in. Green arrow: largest city in Denmark (Copenhagen): mostly recovered. Red arrow: Second largest city in Denmark (Aarhus): mostly infected. Grey arrow: low-population area: mostly susceptible (i.e. have not been infected). (c) Number of infected individuals as a function of time. Data shown for the spatially distributed network ($\rho = 0.1 \text{ km}^{-1}$). Simulation was repeated 10 times. (d) Cumulative sum of individuals who have had the disease as a function of time (with $\rho = 0.1 \text{ km}^{-1}$). (e) Relative difference in maximal number of infected, I_{peak} , between deterministic (SEIR) and ABM as a function of ρ , and shown for different parameters. Note the data for $\beta = 0.007$ are shown in blue with a factor 10 scaling (right y-axis). (f) Relative difference in total number of infected at the end of the epidemic, R_{∞} , between deterministic (SEIR) and ABM as a function of ρ . Colours similar to (e). (g) Same as (e), but as a function of ϵ_ρ . (h) Same as (f), but as a function of ϵ_ρ .

(i.e. including *super connectors*). This leads to a significant effect for $\rho = 0 \text{ km}^{-1}$, which converges towards the other curves for $\rho > 0.1 \text{ km}^{-1}$ (orange (only super connectors) and green (super connectors and super shedders) points in figure 2e). The total number of individuals that have been in the infectious state, when there are not enough susceptible agents for the disease to keep infecting new individuals, is termed R_{∞} , and this converged towards half of the SEIR model prediction as a function of ρ except for $\beta = 0.007$ where the endemic steady state level is larger than the one obtained by the SEIR model (figure 2f). We note that in reality, individuals can lose immunity and therefore new waves can emerge. But for a completely susceptible population, R_{∞} describes the fraction of the population that will get the disease during a specific wave. Fixing $\rho = 0.1 \text{ km}^{-1}$ and increasing the fraction of distance-independent contacts, ϵ_ρ , we found that $I_{\text{peak}}^{\text{ABM}}$ is almost unaffected for $\epsilon_\rho < 0.5$ (figure 2g), while R_{∞}^{ABM} increases linearly towards the SIER model R_{∞}^{SEIR} , as expected (figure 2h).

2.2. Fitting early infection curves leads to significant bias in estimating the size of the pandemic

Next, we consider how these heterogeneities bias the traditional SEIR model predictions, especially the predictions based on fits to the number of infected (i.e. the curve to be flattened) in the beginning of the epidemic (see Methods). Without spatial dependence, the predicted curves fitted the number of infected

individuals very well (figure 3a). Introducing spatial dependence ($\rho = 0.1 \text{ km}^{-1}$) leads to a severe overestimation of the epidemic based on the number of early infection cases (figure 3b). This result can be interpreted by the fact that in societies where population density and thus individual contact number varies significantly, the early phase will be driven by people with many contacts (*super connectors*). This typically happens in cities where the population density is high. Increasing the spatial dependence ρ , we found that the SEIR model predictions overestimated the infection peak height I_{peak} and the total number of infected R_∞ significantly even for very small spatial heterogeneities (figure 3c, d). We observed this general trend for all tested combinations of parameters and heterogeneities. In particular, we found that if long-distance connections ϵ_ρ are below 10%, the bias in the estimated infection peak height, I_{peak} , was constant within statistical uncertainty (figure 3e). For the total number of infected, R_∞ , we observed an almost linear regression to the SEIR model as ϵ_ρ approaches one. However, even when $\epsilon_\rho = 0.25$, the prediction bias was still a factor of two (figure 3f). We concluded from these curves a general trend; if one fits an SEIR model to infection numbers during the beginning of an epidemic, and use these estimates to predict the characteristics of the epidemic at a national level, one overestimates the number of infected by at least a factor of two.

3. Discussion

In summary, this work outlines that the degree of population clustering in Denmark creates a discrepancy between the early predictions made by the SEIR models and the underlying agent-based interactions. It results in a significant overestimation of the impact of the disease, both in terms of maximal number of simultaneously infected (by a factor of 3) and the endemic steady state level (by a factor of 2.5). Such discrepancies have been observed for earlier pandemics, for instance, the 1918 Spanish flu, where the predicted number of individuals that would get the disease within a season turned out to be higher than the actual outcome [35]. The present results can be an important element in explaining these mismatches, even though other elements, such as for instance social distancing and the population behaviour, play a vital part. When facing a rising pandemic, societies are faced with the task of laying out strategies to minimize the consequences, including the importance of *flattening the curve*. While this is truly crucial to avoid overpopulated hospitals, the understanding of the pandemic should be taken seriously enough that we might specify to a higher degree of certainty which curve to be flattened. Our results highlight an important element in the prediction of infection levels and quantify the effect of density heterogeneities. We are aware that these results are not directly applicable to the pandemic of SARS-CoV-2 as a whole, since numerous mutations have increased the infection rates compared to the early estimates and created a strong heterogeneity in the infection worldwide. Furthermore, the actual evolution of the pandemic was highly affected by the different governmental interventions, that are not included in this work. However, this study emphasizes the abnormally large reproduction rates in the beginning of a pandemic, due to individuals with more connections than the rest of the population and attempts to quantify this bias, when countries should estimate the severity of a disease based on the data collected in the early phase. This also underlines the benefits by making lockdowns early in the pandemic, when a population is highly susceptible (for instance to a new mutation) and therefore can be driven by *super connectors*. Since people living in city-clusters are more likely to have many contacts, or infection events, they are on average more likely to be affected in the early stage of the pandemic (if they do not implement social distancing). By removing contacts from these individuals, through some level of interaction in order to reduce the number of social contacts, one can avoid the worst peak while affecting the lowest number of people. While our work describes some fundamental aspects of the disease spreading, this model does not consider asymptomatic individuals, which has been an important aspect of the SARS-CoV-2 pandemic [36,37]. Effectively, asymptotic individuals would correspond to a very heterogeneous distribution of time the agents spend in the infectious state. While agents with symptoms would predominantly isolate themselves and thereby significantly reduce their ability to infect other agents, asymptomatic agents would have a long time in the infectious state, thereby infecting more individuals. In this work, we have not considered the observation that individuals lose their immunity to SARS-CoV-2 which was first studied in the Brazilian city of Manaus. For this model, the temporal decline of immunity would lead to more pandemic ‘waves’, but for a fixed disease transmissibility this would not alter the maximal height of the peak number of infected, since this occurred for all the initially susceptible population. Finally, we note that this work does not include a vast range of divisions for the population, including age, socio-economic status etc. We have not included this directly, since we wanted to estimate as cleanly as possible how the heterogeneity in the

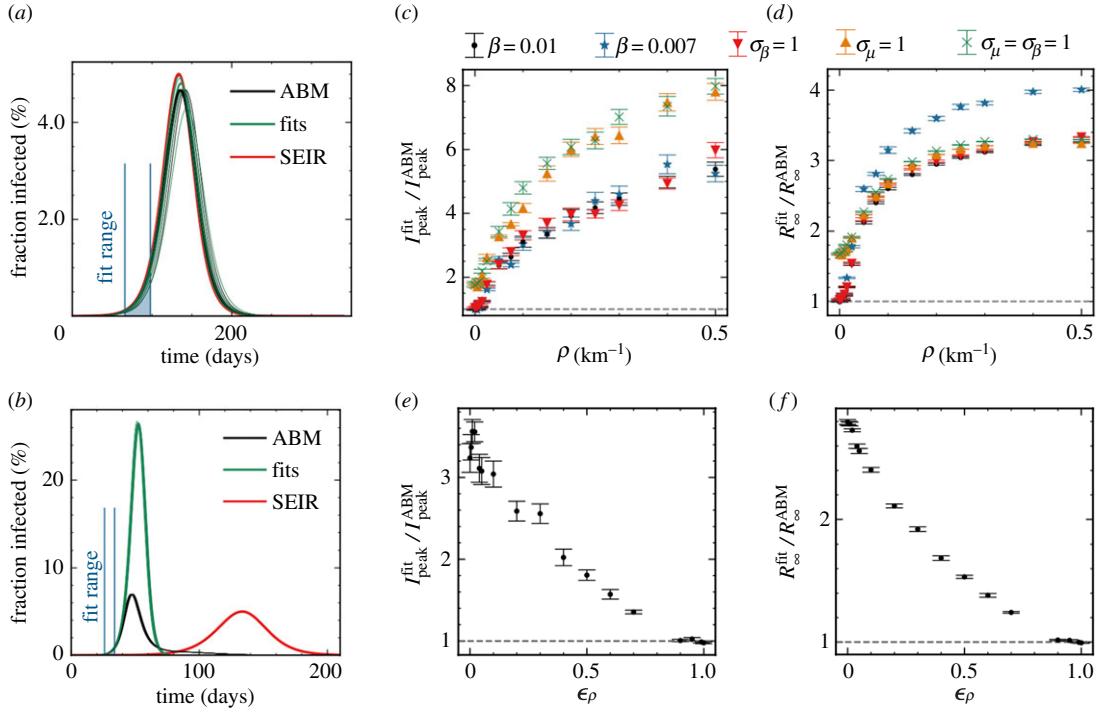

Figure 3. (a) Number of infected individuals for the ABM in black, the SEIR model in red and the SEIR fits to the ABM data in green. Blue lines show the interval where parameters are fitted (also shown below the curves). Here, $\rho = 0 \text{ km}^{-1}$. (b) Same as (a) but with population clustering ($\rho = 0.1 \text{ km}^{-1}$). (c) Relative difference in maximal number of infected, I_{peak} , between the fit and the ABM for different values of ρ . Simulations repeated 10 times for each data-point. (d) Relative difference in total number of infected at the end of the epidemic, R_{∞} , between the fit and the ABM for different values of ρ . (e) Same as (c), but as a function of ϵ_{ρ} . (f) Same as (d), but as a function of ϵ_{ρ} .

contact pattern, arising from a geographically distributed population, could affect the evolution of a disease. We are aware that for instance the distribution of age has an enormous impact on the health risk and that this risk is vital in the prediction of hospitalizations in modern society. However, our aim was to understand the bias in the prediction of a disease, based on the data that comes during the early periods of a disease, independently of the mortality of this disease. Mathematical predictions of disease progression have been heavily criticized [38,39] and it is important to improve the theoretical foundations of the mathematical descriptions, in order to increase the confidence in the predictions. Our work highlights the importance of estimating the spatial clustering and connectivity skewness in the population in order to correct the predictions based on SEIR models, by quantifying their biases from not including spatial clustering. We hope that this work could serve as an input to the modelling and prediction of future pandemics and the importance of avoiding super-spreaders in high-density areas.

3.1. Methods

3.1.1. Construction of spatial network

We initialized N_0 agents on a network generating a total of $\mu \times N_0$ links between two agents, with an assigned interaction strength β_{ij} for each link. The average contact number, μ , was fixed to 20, based on results from the Danish HOPE project, gathering data on population behaviour since April 2020 [34]. In order to include a realistic, geographical distribution of the population, we randomly selected agent locations from a two-dimensional kernel density estimate we had generated based on housing sales in Denmark 2007–2019 (data given with permission from Boligsiden, [33]). We note that in this distribution, we do not take specific geographical elements such as roads or environment into account (which has been previously studied for other diseases [40]) as we assume that this effect is small in a country like Denmark, where all parts are connected and natural obstacles such as mountains and rivers are not present. To connect the agents, we used a hit and miss method, where two random agents are first suggested and then connected with probability, $p(d) = e^{-\rho d_{ij}}$. Here, d_{ij} is the distance between agents and

ρ is a parameter with units of inverse distance. We choose $\rho = 0.1 \text{ km}^{-1}$ (i.e. 10 km) which is the average distance travelled by labour force (statistics Denmark [23]). To allow some long-distance interactions, we introduced a parameter $\epsilon_\rho = 4\%$ representing the fraction of distance-independent connections. This value is based on the fraction of workers travelling longer than 50 km to work (statistics Denmark [23]).

3.1.2. Fits and predictions

We defined an early phase to be the period of time when between 0.1% and 1% of the population were infected (blue lines figure 3a). We then fitted β and a time delay, τ , to the SEIR model with a χ^2 -fit (assuming Poissonian statistics) and kept λ_E and λ_I fixed to the true numbers (used in the simulation). The initial number of infected, N_{init} , was also fixed to the true numbers. The fit parameters were then inserted into the SEIR model, and $I_{\text{peak}}^{\text{fit}}$ and R_{∞}^{fit} were extracted from the fitted model and compared to the $I_{\text{peak}}^{\text{ABM}}$ and R_{∞}^{ABM} from the ABM simulation.

Abstract

In order to obtain fine-tuned regulation of protein production while maintaining cell integrity, it is of fundamental importance to living organisms to express a specific subset of the genes available in the genome. One way to achieve this is through the formation of subcompartments in the nucleus, known as foci, that can form at various locations on the DNA fibers and repress the transcriptional activity of all genes covered. In this work we investigate the physical nature of such foci, by applying single molecule microscopy in living cells. Here we study the motion of the protein SIR3. By combining various statistical methods, and combining a frequentist with a bayesian approach, we extract the diffusion properties for motion in a repair foci. In order to obtain useful information based on this, we derive similar measures for the foci itself, the motion of SIR3 outside the foci and other mutants of the cell. We reveal that the behaviour inside a repair foci is highly immobile and we compare this to theoretical expressions. Based on this we hypothesize that the repair foci is probably not a result of a second order liquid-liquid phase separation but rather a so-called Polymer Bridgng Model with numerous binding sites.

2 | METHODS & MATERIALS

2.1 | Diffusion model

40 For each of the different types of data (XXX), we load in the cells and group them by cell number
 41 and ID. For each group we compute the distance Δr between the subsequent observations \vec{x}_i :

$$42 \quad \Delta r_i = \|\vec{x}_{i+1} - \vec{x}_i\|. \quad (1)$$

43 E.g., for Wild Type 1, we find 914 groups across 43 different cells, leading to a total of $N = 10.025$
 44 distances. We model the diffusion distances with a Rayleigh likelihood, where the Rayleigh distri-
 45 bution is given by:

$$46 \quad \text{Rayleigh}(x; \sigma) = \frac{x}{\sigma^2} e^{-x^2/(2\sigma^2)}, \quad x > 0. \quad (2)$$

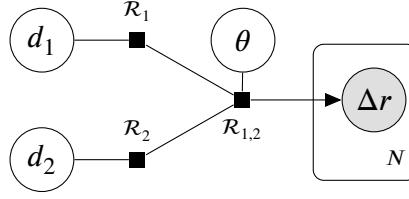

Figure 1. A graphical representation of the Bayesian model case of two diffusion components using the directed factor graph notation (Dietz, 2022). Here d_1 is the diffusion coefficient, \mathcal{R}_1 is the d -parameterized Rayleigh distribution and $\mathcal{R}_{1,2}$ is the mixture model of the Rayleigh distributions with a θ prior.

In this study, we parameterize the Rayleigh distribution in terms of the diffusion coefficient d , which
50 is related to the scale parameter σ in eq. (2), through the XXX parameter, τ :

$$\sigma = \sqrt{2d\tau}, \quad (3)$$

52 with $\tau = 0.02$ in the current study. In the simplest form, where we assume only a single diffusion coefficient, d , the Bayesian model for this process is:

54 [d prior]	$d \sim \text{Exponential}(0.1)$
[transformation]	$\sigma = \sqrt{2d\tau}$
56 [likelihood]	$\Delta r_i \sim \text{Rayleigh}(\sigma)$.

58 A more realistic diffusion model include more than a single diffusion coefficient. Figure 1 shows this for the two-component case in directed factor graph notation (Dietz, 2022). In particular, the
60 figure shows the combination of the $K = 2$ diffusion coefficients d_k through a mixture model $\mathcal{R}_{1,2}$ of the two d -parameterized Rayleigh distributions \mathcal{R}_k with a θ -prior. We model each of the distances
62 as independent, indicated by the N -replications plate. In equations, the figure is similar to:

[d_1 prior]	$d_1 \sim \text{Exponential}(0.1)$
64 [d_2 prior (ordered)]	$d_2 \sim \text{Exponential}(0.1), \quad d_1 < d_2$
[$\bar{\theta}$ prior]	$\theta_1 \sim \text{Uniform}(0, 1), \quad \bar{\theta} = [\theta_1, 1 - \theta_1]$
66 [mixture model]	$\mathcal{R}_{1,2}(d_1, d_2, \bar{\theta}) = \text{MixtureModel}([\mathcal{R}(d_1), \mathcal{R}(d_2)], \bar{\theta})$
68 [likelihood]	$\Delta r_i \sim \mathcal{R}_{1,2}(d_1, d_2, \bar{\theta}).$

2.2 | Model comparison

70 We can generalize the $K = 2$ diffusion model to higher values of K by having d_1, \dots, d_K (ordered such that $d_1 < d_k < d_K$) to prevent the classical label-switching problem in the case of mixture mod-

72 els (McLachlan and Peel, 2004)) diffusion coefficients and letting the mixture model's $\bar{\theta}$ -prior be a
 73 random variable from a flat Dirichlet distribution (such that $\sum_k \theta_k = 1$). We find that including up
 74 to three diffusion coefficients yields appropriate results. To compare the three models of differ-
 75 ent complexity, we compute the Widely Applicable Information Criterion (WAIC) (Watanabe, 2010)
 76 which is a generalized version of the Akaike information criterion (AIC) useful for Bayesian model
 77 comparison (Gelman, Hwang, and Vehtari, 2014). In short, the WAIC is an approximation of the
 78 out-of-sample performance of the model and consists of two terms, the log-pointwise-predictive-
 79 density, lppd, and the effective number of parameters p_{WAIC} :
 80

$$\text{WAIC} = -2 (\text{lppd} - p_{\text{WAIC}}). \quad (6)$$

The lppd is the Bayesian version of the accuracy of the model and p_{WAIC} is a penalty term related to
 81 the risk of over-fitting; complex models (usually) have higher values of p_{WAIC} than simple models,
 82 (McElreath, 2020). The minus 2 factor is just a scaling included for historical reasons leading to low
 83 WAICs being better. Given two models, A and B, we compute both the individual WAIC values, W_A
 84 and W_B , their standard deviations, σ_{W_A} and σ_{W_B} , their difference, $\Delta_{A,B}$, and the standard error of
 85 their difference, $\sigma_{\Delta_{A,B}}$.
 86

2.3 | MSD and energy

87 After choosing the optimal model, we extract the slow diffusion coefficient from the model, d_{slow} ,
 88 and use this to compute the mean squared displacement (MSD) for the groups with a mean diffu-
 89 sion $D = \langle \frac{\Delta r^2}{4\tau} \rangle$ being slow, where slow is defined as $D < d_{\text{slow}} + 3\sigma_{\text{slow}}$. From the MSD, we can either
 90 infer the full XXX (Mathias) model, based on XXX equation:
 91

$$4\sigma^2 + R_\infty^2 \left(1 - \exp \left(-\frac{4dx}{R_\infty^2} \right) \right) \quad (7)$$

or simply approximate the DCon2_WT1 (XXX) with half of the slope of the first three data points of
 92 the MSD (Mathias, why half?).
 93

We can compute the energy, U , in two different ways; U_{left} and U_{right} . The first method is based
 94 on a geometric calculation depending on the fraction of the slow diffusion coefficient from the Wild
 95

Type 1 calculation, $\theta_{\text{slow}}^{\text{WT1}} \equiv \theta_1^{\text{WT1}}$:

98

$$\begin{aligned} V_{\text{cap}} &= \frac{\pi h^2}{3(3r_0 - h)} \\ V_0 &= \frac{4\pi}{3 - 2V_{\text{cap}}} \\ V_F &= \frac{8V_0}{4\pi/3} \frac{4\pi}{3R_R^3} \\ U_{\text{left}} &= -\log \left(\theta_{\text{slow}} \frac{V_0 - V_F}{(1 - \theta_{\text{slow}}^{\text{WT1}})V_F} \right), \end{aligned} \tag{8}$$

where $r_0 = 1.0$, $h = 0.85$, and $R_R = 0.13$.

100

The other energy, U_{right} , can be calculated from the value of DCon2_WT1 (half slope) from Wild Type 1, the Db_focus (half slope) from the Focus files, and the fast diffusion coefficient from the delta files: $\theta_{\text{fast}}^{\text{delta}} \equiv \theta_2^{\text{delta}}$:

102

$$U_{\text{left}} = \log \left(\frac{\text{DCon2_WT1} - \text{Db_focus}}{\theta_{\text{fast}}^{\text{delta}} - \text{Db_focus}} \right). \tag{9}$$

104

2.4 | Implementation

106

The data analysis has been carried out in Julia (Bezanson et al., 2017) and the Bayesian models are computed using the Turing.jl package (Ge, Xu, and Ghahramani, 2018). We use Hamiltonian Monte Carlo sampling (Betancourt, 2018) with the NUTS algorithm (Hoffman and Gelman, 2011).
108 In particular, each Bayesian model have been run with 4 chains, each chain 1000 iterations long after discarding the initial 1000 samples ("warm up").

110

3 | RESULTS

3.1 | Dynamics of SIR3 reveals two dominating populations of the motion

112

We started out by investigating the mobility of individual SIR3 molecules in vivo. Here we typically have 5-8 repair foci. To image SIR3 without changing its normal level, we generated haploid cells expressing the endogenous SIR3 fused to Halo (Figure 1A). Before we wanted to visualize the cells on a PALM microscope (see Materials and methods), we incubated the exponentially growing cells with fluorescent and fluorogenic JF647, a dye emitting light only once bound to SIR3. We were very used a low concentration of JF646 allowing for the observation of individual molecules (Ranjan et al., 2020; Figure 1— figure supplement 2). Rad52-Halo bound to JF646 (Rad52-Halo/JF646) were visualized at 20 ms time intervals (50 Hz) in 2-dimensions during 1000 frames until no signal was visible.

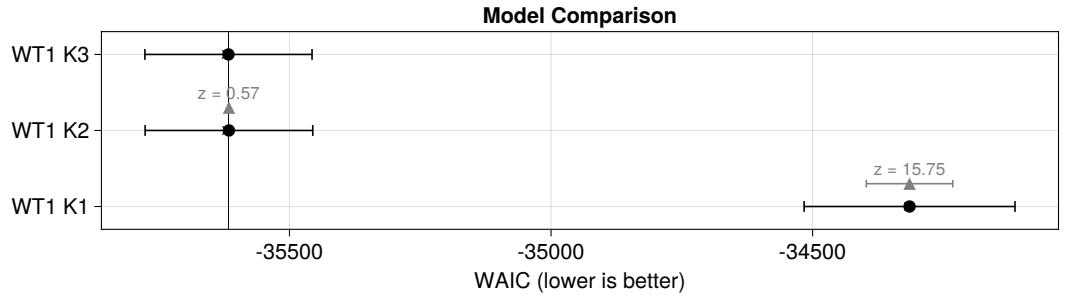

Figure 2. Comparison between diffusion models with $K = 1$, $K = 2$, or $K = 3$ diffusion coefficients for the Wild Type 1 data (WT1). The x-axis shows the WAIC score, where lower values indicate higher-performing models. The WAIC-score for each model is shown in black along with its uncertainty. The difference in WAIC-scores between the model and the best performing model (WT1 K3) is shown in grey with z being the number of standard deviations between them.

3.2 | Bayesian Analysis

122 Comparing the three diffusion models with 1, 2, or 3 diffusion coefficients, respectively, we find that
 123 the model with only a single diffusion component is simply not advanced enough to fully explain
 124 the data, see Figure 2. This figure shows that, even though the 3 component model is the best-
 125 performing of the models, when judging by the number of standard deviations, z , that the best
 126 model's WAIC is higher than the second best model's WAIC, it is statistically non-significant ($z < 2$).
 Since the performance of both the 2 and 3 component models are indistinguishable, we follow
 128 Occam's razor and continue with the former model.

Bayesian models allow for far greater flexibility than traditional frequentist models, including
 130 internal validation checks and diagnostic criteria to make sure that the model has not converged.
 In particular, we made sure that all \hat{R} -values were less than 1.01. To fully validate the $K = 2$ model,
 132 we show the traceplots and posterior distributions for the different parameters in Figure 3. The
 left part of the figure shows the parameter estimate as a function of MCMC iteration, i.e. traceplot,
 134 which, for correctly sampled chains, should resemble a fuzzy caterpillar (and not a skyline which
 would indicate bad mixing) (Roy, 2020). We find that the slow diffusion coefficient for WT1 data is:
 136 $\theta_{\text{slow}}^{\text{WT1}} = 0.0417 \pm 0.0014 \text{ XXXunit.}$

XXX Energy computation shows that, see Figure 4.

138 Final results:

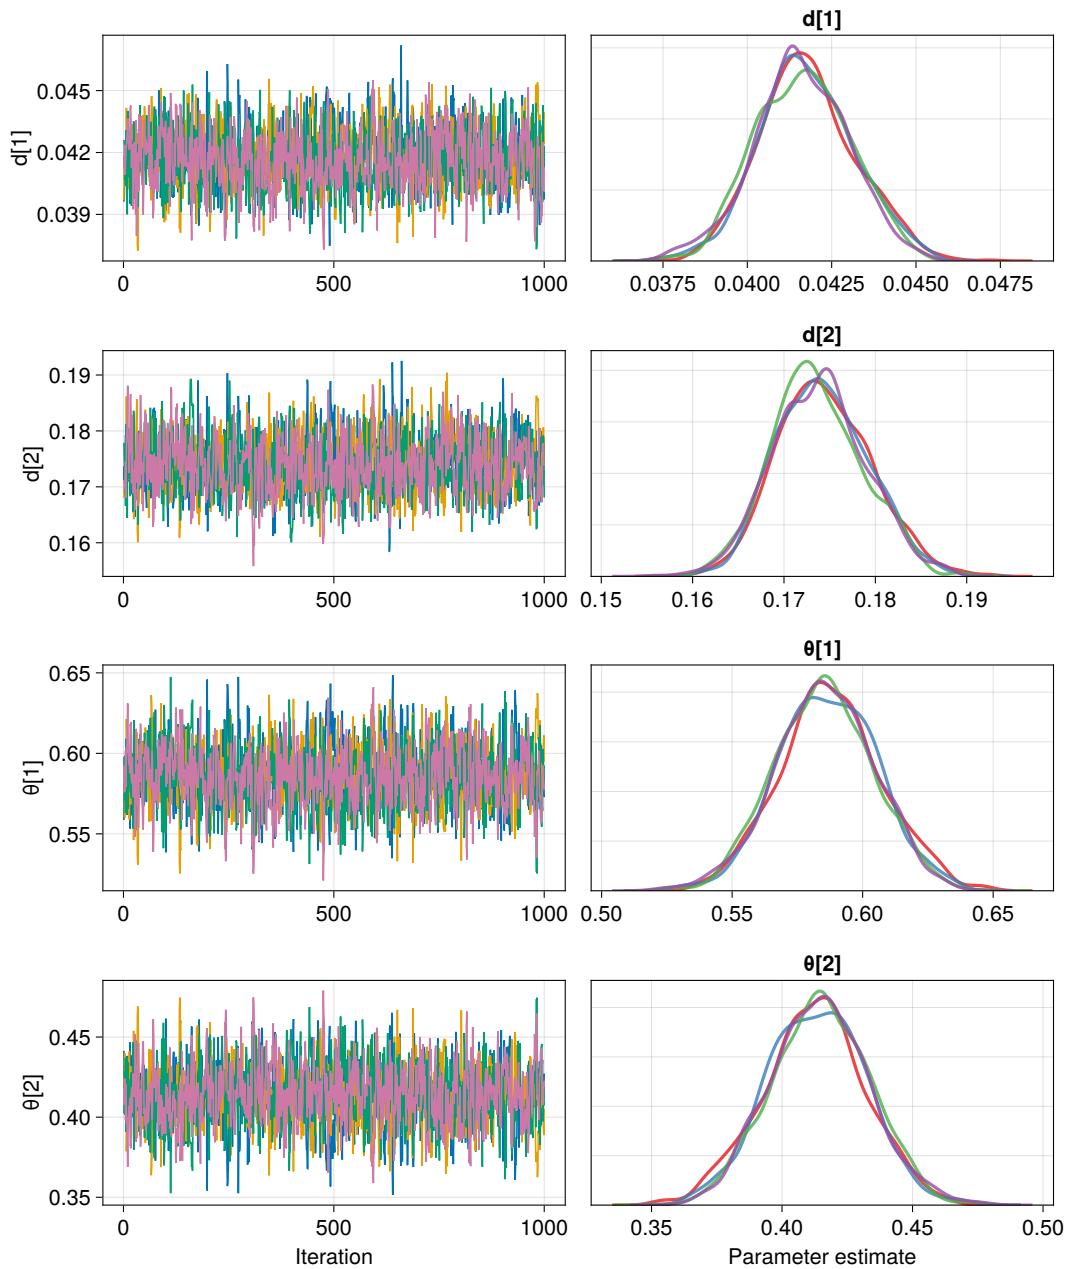

Figure 3. Results of the $K = 2$ diffusion model. Left) Traceplots. Right) Density plots.

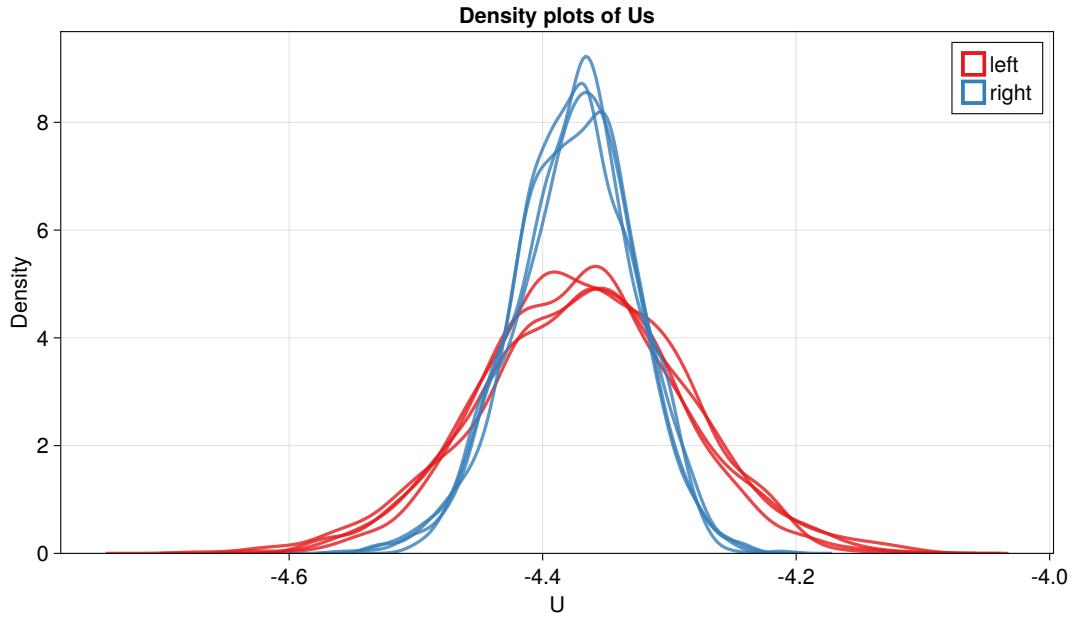

Figure 4. Density plot of the energy, U , using either the left or the right computation approach (XXX Mathias). The energy computed using the left computation is shown in red, and in blue with the right computation. The four different MCMC chains (for each approach) are shown as individual lines.

$$\text{DCon1_WT1} = 0.010\,29 \pm 0.001\,83$$

$$\text{DCon2_WT1} = 0.017\,334\,3 \pm 0.000\,000\,4$$

$$\text{Db_focus} = 0.006\,629\,0 \pm 0.000\,000\,1$$

$$U_{\text{left}} = -4.373 \pm 0.078$$

$$U_{\text{right}} = -4.375 \pm 0.047$$

$$\text{Din_hyper_WT} = 0.031\,51 \pm 0.002\,71 \quad (10)$$

$$\text{DCon1_hyper_WT} = 0.008\,14 \pm 0.002\,34$$

$$\text{DCon2_hyper_WT} = 0.015\,391\,1 \pm 0.000\,001\,8$$

$$\text{Db_hyper_focus} = 0.001\,315\,7$$

$$U_{\text{left-hyper}} = -4.364 \pm 0.204$$

$$U_{\text{right-hyper}} = -4.108 \pm 0.047$$

1. Sammenfatning og konklusion

I indeværende rapport har modelgruppen for matematisk modellering af COVID-19 estimeret hvilke delelementer af kontaktopsporing, som er afgørende for at opnå størst mulig effekt af kontaktopsporing af nære kontakter til COVID-19 smittede personer.

Rapporten præsenterer resultater fra to forskellige agentbaserede modeller, som er udviklet af eksperter fra Danmarks Tekniske Universitet (DTU) og Københavns Universitet, Niels Bohr Institutet (NBI).

En agentbaseret model gør det muligt at modellere enkelte tiltag og deres effekt på smittespredningen af COVID-19. Forudsætningen for en præcis simulation er, at der er tilgængelige data, som kan informere modellen. Der er flere parametre, hvor der i nærværende arbejder er lavet antagelser på basis af de tilgængelige oplysninger. Det forventes, at nogle af disse kan belyses efterhånden som yderligere data frembringes. Hvor der ikke er specifikke eller komplette data, vil en agentbaseret model have unøjagtigheder eller risikere at være baseret på antagelser, som ikke nødvendigvis er retvisende. I modellerne anvendes der endvidere ens ventetidsfordelinger for alle agenter, selvom der i realiteten kan være lokale udsving i ventetider.

Sundhedsstyrelsen udkom d. 23. november 2020 med opdaterede retningslinjer for smitteopsporing af nære kontakter, herunder en udvidet definition af nære kontakter. Indevarende rapport er udviklet i henhold til de tidligere retningslinjer, og tager ikke højde for disse ændringer.

Der er i rapporten heller ikke taget højde for den stigende brug af private antigen test. Coronaopsporingen under STPS foretager også opsporing af nære kontakter, for primært tilfælde som er testet positiv for COVID-19 på sådanne antigen test.

Konklusion

Modellerne peger på, at den største reduktion i kontakttallet kan nås ved effektiv opsporing for flest mulige primært tilfælde. Gevinsten i form af en reduktion i kontakttallet er således større, såfremt der sikres effektiv opsporing for samtlige primært tilfælde, relativt til reduktionen i kontakttallet, som kan opnås ved at nedbringe ventetiden til test og testsvar for primært tilfældet.

Ventetiden til test og testsvar for et primært tilfælde med COVID-19, har stor betydning for den reduktion af kontakttallet, som kan opnås gennem kontaktopsporing. De to uafhængigt udviklede modeller fra hhv. DTU og NBI finder begge, at for hver dag ventetiden til test og testsvar forsinkes for primære tilfælde, stiger kontakttallet med 4%. DTU-modellen finder endvidere, at ventetiden til et primært tilfælde booker en test og samtidig går i isolation har stor betydning for reduktionen i kontakttallet.

Modellerne viser endvidere, at med de anvendte ventetidsfordelinger, vil størstedelen af de nære kontakter som opspores, bliver testet så sent, at det er en mindre del af smitten, som forhindres. Det er derfor vigtigt at opspore nære kontakter hurtigst muligt efter eksponering, så de kan isoleres og blive testet på dag 4 og 6. Dette vil igen afhænge af den samlede ventetid til test og testsvar for primært tilfældet, som er forudsætningen for at opsporingen af nære kontakter kan initieres.

Den agentbaserede model fra NBI finder, at der er yderligere gevinst at hente ved at opspore nære kontakter i de netværk en person indgår i uden for husstand, job og skole. Det skyldes, at relativt få kontakter uden for husstand, job og skole opspores, og at disse kontakter ofte starter nye smittekæder i ikke ellers relaterede netværk. En bredere smitteopsporing har den fordel, at den potentielt finder de nye smittede, som ikke udviser symptomer.

2. Formål og baggrund

2.1 Formål og baggrund for modelgruppen

Statens Serum Institut indgår i det operationelle beredskab for smitsomme sygdomme og yder rådgivning og bistand til regeringen i forbindelse med den aktuelle pandemi. Som en del af denne opgave har Statens Serum Institut nedsat og leder en ekspertgruppe, der har til formål at udvikle matematiske modeller til at belyse udviklingen i COVID-19 i Danmark. Medlemmerne af ekspertgruppen fremgår af bilag 5.

Ekspertgruppens modellering var i foråret 2020 baseret på en populationsmodel, der har fokus på den gennemsnitlige adfærd i befolkningen. Populationsmodellen er bedst egnet, når udviklingen beskrives godt ved gennemsnittet. Derimod er populationsmodellen ikke det bedste værktøj til at beskrive de stokastiske hændelser i lokale udbrud, som aktuelt driver smittespredningen af COVID-19 i Danmark.

Siden sommeren 2020 har modelgruppen derfor udviklet to agentbaserede modeller, som er platformen for de analyser, modelgruppen forventes at levere i den kommende periode. De agentbaserede modeller kan, modsat en populationsmodel, estimere effekten ved enkelte tiltag, såsom effekten ved at nedbringe forsamlingsforbuddet, eller effekten af kontaktopsporing.

2.2 Formål med rapporten

Opsporingen af nære kontakter, foretaget af Styrelsen for Patientsikkerhed (STPS), er løbende udbygget i Danmark siden foråret 2020. Opgaven er vokset betydeligt i takt med, at det daglige antal nye COVID-19 tilfælde stiger, som følge af både en opblussen af epidemien, men også af, at testkapaciteten i Danmark er væsentligt udbygget hen over sommeren. Der testes aktuelt omkring 70.000 personer dagligt.

Formålet med denne rapport er at belyse, hvilke faktorer der er afgørende for at sikre en effektiv kontaktopsporing. Dette blyses ved at estimere effekten af centrale elementer i kontaktopsporringen, såsom ventetid til test og testresultat hos primærtildældet, samt ventetid til at nære kontakter bliver opsporet og testet.

3. Opsporing og håndtering af nære kontakter i Danmark

3.1 Forudsætninger for en effektiv kontaktopsporing

Den vigtigste forudsætning for, at kontaktopsporing er et effektivt redskab til at nedbringe smitten med COVID-19 er, at der til hver en tid identificeres flest mulige smittede personer, som der derved kan udføres smitteopsporing for. Jo lavere mørketallet er, desto flere vil kunne smitteopspores. Det er derfor afgørende, at der sikres nem og hurtig adgang til test, først og fremmest for personer med COVID-19 lignende symptomer, men også for øvrige personer, der kunne have misitanke om at være smittet med COVID-19. Den Nationale Prævalensundersøgelse i Danmark har vist, at op mod 40-50% af dem, som havde antistoffer mod SARS-CoV-2 i blodet, ingen erindring havde om at have haft COVID-19 lignende sygdom¹. Ved at udbyde adgang til test for flest mulige personer, vil man også finde flere asymptomatiske smittebærere.

3.2 Definition af en nær kontakt

Sundhedsstyrelsen udkom d. 23. november 2020 med opdaterede retningslinjer for smitteopsporing af nære kontakter. Indeværende rapport er udviklet i henhold til de tidligere retningslinjer.

Der er således ikke taget højde for den udvidede definition af nære kontakter, eller indførslen af screeningsprøver for personer, som ikke umiddelbart opfylder kriteriet for nære kontakter, men som har været eksponeret i et omfang hvor der tilrådes en screeningstest.

Kontaktopsporingen af nære kontakter baserer sig på, at personer der testes positiv for COVID-19 isolerer sig, og dernæst at nære kontakter til den smittede opspores, isoleres og testes, for dermed at afbryde smittekæder hurtigst muligt.

Definitionen af en nær kontakt er beskrevet i Sundhedsstyrelsens rapport om smitteopsporing af nære kontakter².

En nær kontakt er defineret som en af følgende personer:

- En person der bor sammen med en, der har fået påvist COVID-19
- En person der har haft direkte fysisk kontakt (fx kram) med en, der har fået påvist COVID-19
- En person med ubeskyttet og direkte kontakt til smittefarlige sekreter fra en person der har fået påvist COVID-19
- En person der har haft tæt "ansigt-til-ansigt" kontakt inden for en 1 meter i mere end 15 minutter (fx i samtale med personen) med en, der har fået påvist COVID-19
- Sundhedspersonale og andre som har deltaget i plejen af en patient med COVID-19, og som ikke har anvendt værnemidler på de forskrevne måder

¹ <https://www.ssi.dk/-/media/arkiv/dk/aktuelt/nyheder/2020/notat---covid-19-prvalensundersgelsen.pdf?la=da>

² <https://www.sst.dk/da/Udgivelser/2020/COVID-19-Smitteopsporing-af-naere-kontakter>

3.3 Periode for smitteopsporing

Der foretages smitteopsporing for perioden, hvor primærtilfældet vurderes at være smitsom. Smitteperioden er således afgrænset til 48 timer før symptomdebut til 48 timer efter symptomophør. For primære tilfælde der ikke har symptomer på COVID-19, er den smitsomme periode afgrænset til 48 timer før positiv test til 7 dage efter.

3.4 Opsporing af nære kontakter

Nære kontakter til en person der er smittet med COVID-19 kan opspores på følgende måder:

- De bliver kontaktet af STPS's Coronaopsporingen
- De bliver kontaktet ifm. kendte udbrud, eksempelvis på skoler
- De bliver kontaktet direkte af primærtilfældet
- De bliver notificeret om, at de har været tæt på en smittet person via appen Smitte|Stop

Nære kontakter opsporet af Coronaopsporingen

Coronaopsporingen under STPS kontakter smittede mhp. at hjelpe med at identificere og opspore nære kontakter til den smittede. Smittede kan også vælge selv at iværksætte opsporing af nære kontakter, og henviser dem til Coronaopsporingen, hvor de nære kontakter vil modtage rådgivning om, hvornår de bør testes, samt får adgang til at booke test på de pågældende dage.

Aktivitetsrapporter fra STPS viser, at der i hele opsporingsperioden i gennemsnit opspores ca. 5 nære kontakter for hvert primærtilfælde, der foretages kontaktopsporing for. Dette er et samlet gennemsnit for opsporede nære kontakter som STPS opsporer, og som primærtilfældet selv opsporer.

Til sammenligning er det estimeret i HOPE-projektet, at danskere henover sommeren i gennemsnit havde ca. 11 kontakter dagligt. Dette antal er nu faldet til ca. 7 kontakter dagligt, som opfylder kriterierne for en nær kontakt, se bilag 4.

Det skal dog pointeres, at Coronaopsporingen ikke er involveret i opsporing af nære kontakter i relation til udbrud i dagtilbud, skoler, plejehjem og hospitaler. Der vil der være opspored kontakter fra sådanne udbrud, som kontakter Coronaopsporingen for at få rådgivning om hvilke dage de bør testes, samt for at få rekvisitoner til booking af test på de pågældende dage.

Nære kontakter anbefales at blive testet på dag 4 og dag 6 efter vurderet eksponering. Dette relaterer sig til latentiden, som er perioden fra, at man bliver smittet, til at man er smitsom, og virus kan påvises. En person som er opsporet som nær kontakt til en smittet skal ifølge Sundhedsstyrelsens retningslinjer gå i selv-isolation, indtil der foreligger testsvar. Såfremt der foreligger et negativt testresultat på dag 4, kan den nære kontakt bryde isolationen, men skal fortsat testes på dag 6. Hvis testresultatet på dag 4 derimod er positivt, skal den nære kontakt ikke testes igen på dag 6, men forblive i isolation indtil 48 timer efter symptomophør.

Nære kontakter der ikke opspores af Coronaopsporingen

Der vil være nære kontakter, der ikke opspores og rådgives via Coronaopsporingen. Dette kunne fx være nære kontakter, der bliver opsporet af primærtilfældet selv, og som vælger at booke test på coronaprover.dk uden først at have rådført sig med Coronaopsporingen. Det kunne også være personer, som er opsporet via appen Smitte|Stop, eller personer der mener, at de på anden vis

kan være nære kontakter til en smittet – uden nødvendigvis at opfylde kriteriet for at være en nær kontakt.

I oktober måned blev der i alt testet 1.091.966 personer. Heraf havde 62% (n = 675.623) bestilt tid på coronaprover.dk. Blandt disse svarede 58% (n = 391.146) på spørgeskemaet på coronaprover.dk, hvoraf 25% (n = 99.389) anførte, at de blev testet fordi, de var nær kontakt til en smittet (herunder personer som er adviseret af Smitte|Stop app). Kun 13% (n = 12.706) af dem som svarede, at de blev testet fordi de var nær kontakt til en smittet, var testet på én af de rekvisitionskoder, som der anvendes i Coronaopsporingen (Tabel 1). Samlet set blev 45.616 personer testet på én af de rekvisitionskoder som anvendes i Coronaopsporingen i oktober måned, hvor test-positivprocenten var ca. 4%. Til sammenligning var positivprocenten for de personer, der svarede, at de var nær kontakt til en smittet på Coronaprover.dk omkring 2,5 %. Dette indikerer at Coronaopsporingen har større succes med at opspore de korrekte nære kontakter, sammenlignet med hvilс befolkningen selv booker test som nær kontakt, uden forudgående rådgivning fra Coronaopsporingen.

Tabel 1. Oversigt over antal testede i oktober måned 2020.

	Oktober		
	N	Testpositive (1. test)	
		n	%
Testede personer	1.091.966	14.723	1,35
Total antal tests rekvireret via Coronaopsporingen	45.616	1.941	4,26
Bestilt på coronaprover.dk	675.623	10.335	1,53
Svaret på spørgeskema	391.146	5.387	1,38
Ja, nær kontakt til smittet (herunder adviseret på Smitte Stop app)	99.389	2.544	2,56
Rekvireret test via Coronaopsporingen	12.706	524	4,12

4. Agentbaserede modeller

4.1 Om agentbaserede modeller

I indeværende rapport er resultaterne for effekten af kontaktopsporing frembragt fra to forskellige agentbaserede modeller, som er udviklet på henholdsvis Danmarks Tekniske Universitet (DTU) og Niels Bohr Institutet, Københavns Universitet (NBI).

En agentbaseret model simulerer et antal agenter (individer i en population) og deres interaktioner med andre agenter, svarende til de interaktioner som en befolkning normalt viser har. Hver agent er således en person, som er knyttet til en lokation i Danmark, svarende til deres bopæl. Agenterne indgår i flere forskellige netværk, f.eks. husstand, job og skole hvor de har kontakt til andre personer. Desuden har de andre kontakter til tilfældige personer i samfundet i den tid, hvor personen ikke er hjemme, på job eller i skole.

Hvis en agent bliver smittet med SARS-CoV-2, er forløbet for den enkelte agent beskrevet således, at agenten først er eksponeret (E) og derefter infektiøs (I), hvorefter agenten ikke længere er smitsom og betragtes som rask (R). De gennemsnitlige tider i hvert sygdomsstadiu kan findes i bilag 1 og 2.

Hver kontakt som en agent eksponeres for tildeles en sandsynlighed for at blive smittet af en anden agent, hvis denne er smitsom. Sandsynligheden er sat til et niveau, som afspejler den nuværende situation med et kontakttal omkring 1.

Ud fra de ovenstående generelle antagelser simuleres en epidemi. For en mere detaljeret beskrivelse af de agentbaserede modeller, herunder de inkluderede parametre, henvises til bilag 1 (NBI) og 2 (DTU).

4.2 Forbehold

Mens en agentbaseret model kan medtage mere detaljerede dynamikker i en epidemi, så kræver en præcis simulation input fra data, som ofte ikke er tilgængelige eller forefindes, fx hvem en person mødes med i løbet af en dag. Derfor kan en sådan model have unøjagtigheder eller bygge på antagelser, som ikke er retvisende. Det er ikke muligt at kvantificere den nøjagtige størrelse eller effekt af disse potentielle fejlkilder.

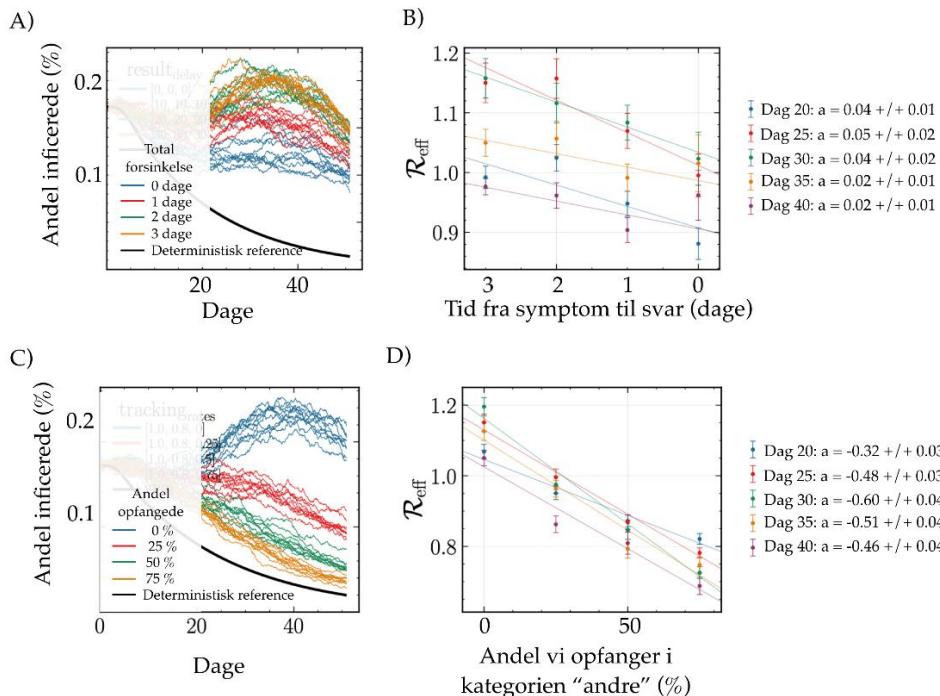

5. Resultater

5.1 Resultater fra den agentbaserede model udviklet af Niels Bohr Institutet, Københavns Universitet.

Modelkørslene viser, at når 80% af de sekundære tilfælde i netværkenes husstande, arbejde og skole opspores, vurderes det, at ville nedsætte kontakttallet med omkring 30% sammenlignet med et hypotetisk scenarie uden opsporing af nære kontakter. Dette fremgår af figur 1. Hvis det af logistiske eller kapacitetsmæssige årsager ikke lykkedes at kontakte alle nye COVID-19 tilfælde, vil det betyde en forøgelse af kontakttallet i proportion til dette tal. Dvs. hvis opsporingen ikke kommer i kontakt med 20% af nye COVID-19 tilfælde, vil man potentielt miste 6 procentpoint ($0.2 \times 0.3 = 0.06$) af reduktionen i kontakttallet, som ellers kunne opnås ved kontaktopsporing.

Ventetiden fra at et primært tilfælde ønsker en COVID-19 test (fx hvis man har symptomer), til at vedkommende har modtaget resultatet fra en test har indflydelse på effekten af både selvisolation og kontaktopsporing. Ved en række simulationer med forskellige antagelser finder modellen, at for hver dag man forkorter tiden mellem bestilling af test og testresultat mindskes kontakttallet med omkring 4%. Effekten er lidt større ved højere kontakttal end 1.

Effekten af kontaktopsporing kan øges ved at opspore flere i netværket af øvrige kontakter (ud over husstand og job og skole). Den agentbaserede model viser, at hvis man opsporer 25% af øvrige kontakter, vil kontakttallet falde med omkring 10%. En mere komplet kontaktopsporing (evt. yderligere hjulpet af apps på mobiltelefoner) vil således nedsætte kontakttallet væsentligt. Tilsvarende resultater er fundet i lignende modeller (Plank et al. (september 2020) og Kretzschmar et al. (august 2020)).

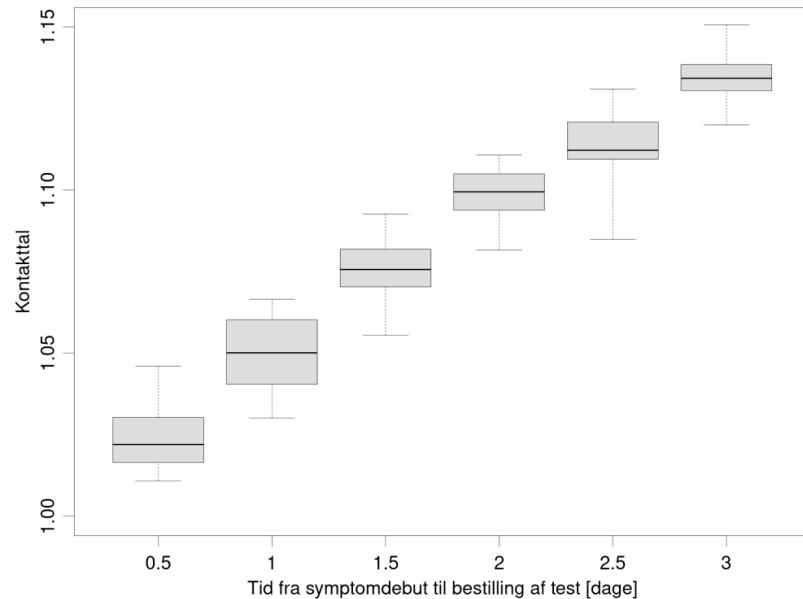

Figur 1: A) Simuleret model, hvor hver kørsel (markeret med samme farve) gentages 10 gange for forskellige værdier af tiden fra symptom til svar. B) Værdien af kontakttallet estimeret på forskellige tidspunkter i simulationen vist i A). Den lineære sammenhæng giver en værdi for hvor mange procent kontakttallet sænkes for hver dag, man gør opsporingen hurtigere. C) Samme som A, men her for forskellige værdier af hvor mange man opsporer blandt øvrige kontakter D) Samme som B) men som funktion af hvor mange man opsporer blandt øvrige kontakter.

5.2 Resultater fra den agentbaserede model udviklet af DTU Compute, Danmarks Tekniske Universitet

Denne agentbaserede model er baseret på tilhørsforhold til grupper (hjem, arbejdsplads, m.fl.). Modellen indeholder en række ventetider fra et primærtiflæde får symptomer til sekundære tilfælde er opsporet. Modellen er nærmere beskrevet i bilag 2. Modellen er kørt med en række forskellige kombinationer af parametre. For hver kombination er der lavet 40 gentagelser for at illustrere variabiliteten. For hver gentagelse simuleres 30 dage som en transient, hvorefter kontakttallet estimeres baseret på de efterfølgende 30 dage.

De to parametre, som betyder mest for effekten af kontaktsporingen, er den gennemsnitlige ventetid fra en smittet får (milde) symptomer til at denne går i isolation og samtidig bestiller en test, samt andelen af kontakter som personen reducerer i perioden fra der bestilles en test til der foreligger et testsvar – det antages, at nære kontakter som opspores opretholder samme grad af isolation som andre, der venter på testsvar, hvilket vil sige, at nære kontakter går i isolation fra de bliver notificeret og indtil de får svar på deres første test.

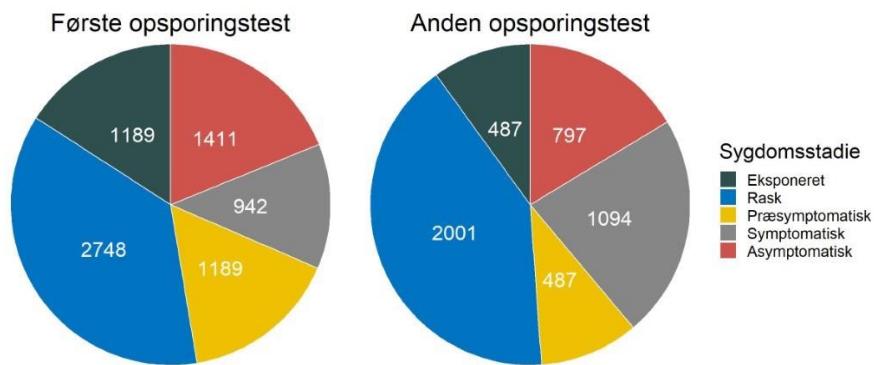

Figur 2: Kontakttallets afhængighed af den gennemsnitlige tid fra at primærtiflædet har symptomdebut til der bestilles en test og personen går i en grad af isolation. For hver parameterværdi er der foretaget 40 simulationer, og boxplottet viser median, de indre kvartiler samt minimum og maksimum af disse.

På figur 2 ses en klar effekt af tiden fra symptomdebut til isolation og samtidig bestilling af test. For hver dag den gennemsnitlige person går hurtigere i (delvis) isolation estimeres det, at kontakttallet reduceres med 0,04 (når referencen er et kontakttal omkring 1).

Modellen viser også, at omkring 25% af alle test positive, er fundet gennem kontaktopsporing. Det er her antaget, at der udføres kontaktopsporing for alle tilfælde (Se detaljer i bilag 2), samt at test af nære kontakter bestilles på de foreskrevne tidspunkter. Endvidere viser modellen, at over halvdelen af alle smittede aldrig bliver testet positiv (både falsk negative test og asymptotiske tilfælde). Disse starter derfor nye smittekæder uden forudgående opsporing. Dette kan være årsagen til, at det kun er 25% som findes gennem kontaktopsporing.

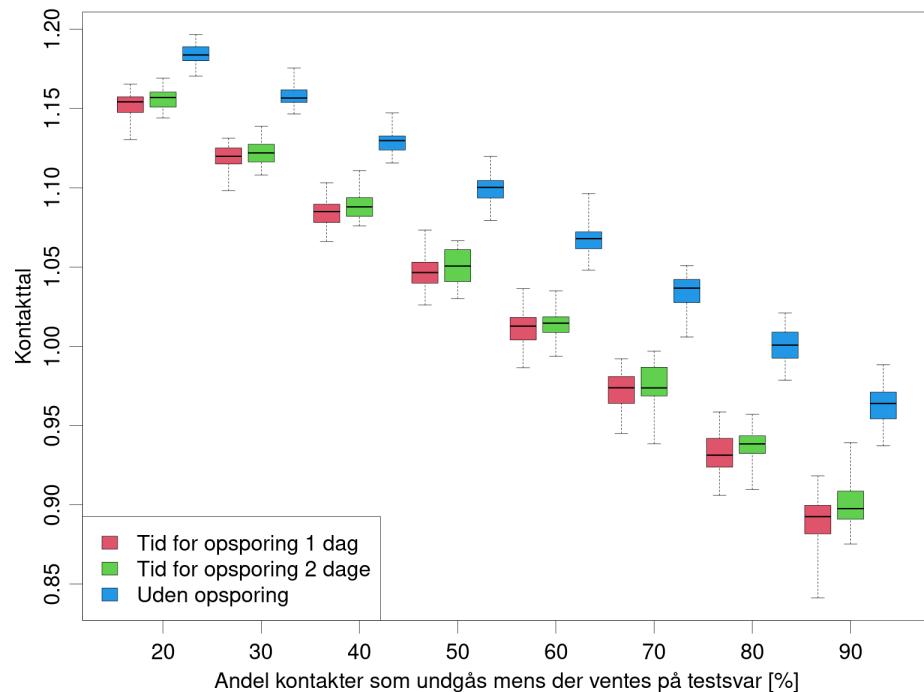

Figur 3. Antal opsporedt og smittede i hvert sygdomsstadi, når de får foretaget hhv. første og anden test i opsporingsprocessen. Der er flere, som ikke kommer til anden test, bl.a. fordi de tester positiv i første test eller efter negativt testsvar vælger ikke at få taget den opfølgende test. Derudover vil der være en andel, hvor kontaktopsporingen er initieret sent, således at det kun er foreskrevet at teste personen én gang.

Figur 3 beskriver de forskellige sygdomsstadier for smittede personer, som er opsporet som nære kontakter. Det ses, at en betydelig andel af de opsporedt personer, med de i modellen anvendte ventetidsfordelinger, på tidspunktet for opsporingen allerede har overstået deres infektiøse periode, når de testes første gang – en del af disse vil være smittet tidligere og ikke i forbindelse med den nærværende kontaktopsporing. I praksis vil nogle af disse teste positiv, da qPCR kan detektere virus 17 dage efter symptomdebut (Cevik et al., 2020). Desuden ses det, at personer i det præsymptomatiske stadi - hvor ca. halvdelen af smitten sker - kun udgør en lille andel af de opsporedt smittede personer ved både første og anden test. Ved begge test er det således under halvdelen af dem, som er smittede, som reelt er infektiøse. Kontaktopsporningen vil derfor kunne optimeres yderligere, hvis man identifierer flere nære kontakter i den præsymptomatiske fase. Dette kan ske ved at nedbringe ventetiden fra symptomdebut til testsvar for primærtildældet.

Personer, som tidligere er testet positiv er ikke medtaget her og bidrager derfor ikke til antallet af raske. Endvidere vil personer som modtager et positivt testresultat på deres første opsporingstest ikke få foretaget anden opsporingstest. Ovenstående diagrammer er produceret på baggrund af referenceparametrene som beskrevet i bilag 2.

Graden hvorved en smittet person isolerer sig, dvs. hvor stor en andel af ens kontakter man reducerer i perioden fra bestilling af test til testsvar, har stor betydning for kontakttallet. Referenceværdien antages at være 50% reduktion i antallet af kontakter i denne periode. Som det fremgår af figur 4 så opnås der i modellen en reduktion i kontakttallet på knap 0,04 for hver 10 procent-point graden af isolation øges, hvis der udføres kontaktopsporing (rød og grøn). Mens reduktionen er på 0,03 når der ikke udføres kontaktopsporing (blå). Således har andelen af kontakter, der reduceres hos primærtilfældet og opsporede nære kontakter i ventetiden fra bestilling af test til testsvar, større betydning for en reduktion i kontakttallet, end en reduktion i ventetiden til opsporing af nære kontakter.

Figur 4. Kontakttallets afhængighed af andelen af kontakter et primærtilfælde og opsporede nære kontakter reducerer, i ventetiden fra der bestilles en test til at testsvar foreligger, samt betydningen af ventetiden til at en nær kontakt opspores og går i tilsvarende isolation. For hver parameterværdi er der foretaget 40 simulationer og boxplottet viser median, de indre kvartiler samt minimum og maksimum af disse.

Bilag 1. Beskrivelse af den agentbaserede model fra Niels Bohr Instituttet

Bidrag og udvikling: Christian Michelsen, Emil Martiny, Tariq Halasa, Mogens H. Jensen, Troels C. Petersen og Mathias L. Heltberg

Den agentbaserede model fra NBI baseres på agenter, dvs. individer hvis karakteristika er tildelt ud fra statistiske fordelinger i befolkningen. Dette er f.eks. en aldersfordeling og en fordeling over pendlerafstande. Modellen starter med at fordele Danmarks bopæle ud i landet baseret på det danske hussalg over de sidste 15 år. Herefter placeres agenter i hver husstand baseret på deres alder og geografiske placering.

Figur 5: A) Skematisk oversigt over hvordan interaktionsnetværket i modellen ser ud. B) Eksempel på simulation af smittespredning i Danmark i modellen, gennem et simuleret tilfælde af flokimmunitet i København.

Et afgørende element i modellen er opbygningen af alle personers interaktionsnetværk. Dette genereres ved, at hver agent har et netværk, de interagerer med. Dette opdeles i tre dele: 1) kontakter i hjemmet, 2) kontakter på arbejdet, 3) kontakter i kategorien andre kontakter. Der er ikke nogen geografisk afhængighed af antallet af kontakter på arbejdet, men i den kategori der kaldes "andre", vil der generelt være flere kontakter for dem der bor i tæt befolkede områder i forhold til dem der bor på landet. Måden hvorpå netværket dannes er vist i Figur 5A.

Ud fra data fra HOPE-projektet har vi estimeret, hvor mange personer hver agent vil interagere med, og i denne model vil alle agenter have mellem 3 og 15 daglige kontakter.

Når modellen simuleres vil alle inficerede agenter gennemgå et forløb, hvor de er i en latent periode, hvor de ikke smitter, hvorefter de vil rykke over i en infektiøs periode, hvor de kan smitte agenter i deres netværk. Denne model simuleres ud fra det der kaldes Gillespie algoritmen, således at netværket opdateres instantant for alle smittebegivenheder. En samling af de væsentligste parametre er vist herunder (Tabel 2).

Tabel 2: Parametre i modellen.

Parameter	Værdi interval for middel-værdien	Reference
Antal kontakter per dag	3-15	HOPE projektet
Latent tid (dage)	3-5	Litteratur se referenceliste i bilag 5
Infektiøs tid (dage)	4-8	Litteratur se referenceliste i bilag 5
Andel af kontakter i “andre” (%)	30-80	HOPE projektet
Typisk afstand mellem kontakter (km)	5-20	Trafik data
Andel afstandsuafhængige kontakter (%)	3-5	Trafik data
Tid fra symptom til test (Dage)	0-2	Fordeling fra spørgeskemaundersøgelse i foråret 2020 (ikke offentliggjort)
Sandsynlighed for at få symptomer og blive testet (%)	20-60 %	Prævalensundersøgelsen
Sandsynlighed for at kontakte husstand (%)	100%	Antagelse
Sandsynlighed for at kontakte kollegaer (%)	40-80	Antagelse
Sandsynlighed for at kontakte andre (%)	0-75	Antagelse

Bilag 2. Beskrivelse af den agentbaserede model fra DTU

Bidrag og udvikling: Freja Terp Petersen, Jacob Bahnsen Schmidt, Kasper Telkamp Nielsen, Rebekka Quistgaard-Leth, Kaare Græsbøll og Lasse Engbo Christiansen

Den agentbaserede model fra DTU baseres på en befolkningstabell, hvor hver række i tabellen svarer til en agent - eller et individ – og hver kolonne indeholder data, der beskriver den pågældende agent, herunder aldersgrupper med 5 års-intervaller, bopælskommune, netværks-ID og forskellige smitteparametre.

I sygdomsmodellen bæres smitten fremad ved, at agenter der deler netværks-ID, f.eks. husholdnings-ID, skole/job-ID eller omgangskreds-ID, kan smitte hinanden. Hver dag får alle agenter udregnet deres sandsynlighed for at blive smittet på baggrund af antal infektioner i deres forskellige netværk og på baggrund af deres individuelle antal nære kontakter, som de er blevet tildelt baseret på en fordeling fra totalt antal kontakter inden for 1m i HOPE projektet.

Der er 7 forskellige netværkstyper, som en agent kan være en del af:

- Husholdning (alle agenter har en husholdning)
- Daginstitution (børn mellem 0 og 4 år)
- Grundskole (børn mellem 5 og 14 år)
- Ungdomsuddannelse (unge mellem 15-24 år samt voksne på erhvervsuddannelser)
- Arbejdsplads med kontorinddelinger (voksne op til 65 år)
- Omgangskreds (alle agenter har en omgangskreds)
- Kommune (alle agenter har en kommune)

Agenterne er blevet tildelt netværk baseret på data fra Danmarks Statistik (husholdninger og arbejdspladser), Undervisningsministeriet (grundskoler og ungdomsuddannelser) samt Institution.dk (daginstitutioner).³ Det antages i modellen, at den gennemsnitlige kontorstørrelse og den gennemsnitlige omgangskreds uden for skole og arbejde er på 8 personer.

Figur 6. Flowdynamisk diagram af bevægelse gennem sygdomsstadier.

Agenter i modellen kan være i et af følgende sygdomsstadier: Modtagelig (S), Eksponeret (E), Præ-symptomatisk (IPS), Symptomatisk (I), Asymptomatisk (A), Rask (R) eller Død (D). Agenter, som befinner sig i det præ-symptomatiske, symptomatiske eller asymptomatiske stadie, er infektiøse og kan således viderebringe smitte til agenter, som befinder sig i det modtagelige stadie. Bliver en modtagelig agent inficeret, overgår de til at være eksponeret. Dette sygdomsstadie repræsenterer den latente periode, hvor den inficerede agent endnu ikke er infektiøs. Agenterne kan bevæge sig gennem sygdomsstadierne, som vist på det flowdynamiske diagram, figur 6. Modellen antager, at 2/3 af agenterne bliver symptomatiske og at 1/3 forbliver asymptomatiske ved infektiøs tilstand. En andel symptomatiske agenter får et behandlingsbehov i løbet af deres sygdomsforløb og bliver indlagt på et Hospital (H). Sandsynligheden for indlæggelse blandt symptomatiske agenter er opdelt efter regioner og 10-års aldersgrupper baseret på data over indlæggelser i Danmark i september-oktober 2020.

Når en agent skifter til et nyt sygdomsstadie, tildeles de den ventetid, som de skal opholde sig i stadiet. Ventetiden i de forskellige stadier er beskrevet ved gamma-fordelinger med parametre, som vist i tabel 3. Modellen simuleres i diskret tid. Hvert tids-skridt svarer til en halv dag.

Tabel 3. Parametre og quartiler for varighed af de enkelte stadier.

Stadier	Parametre		Kuartiler			Referencer
	Shape	Periode [Dage]	Nedre quartil [Dage]	Median [Dage]	Øvre quartil [Dage]	
Eksponeret (E)	3	3	2	3	4	Litteratur se referenceliste i bilag 5
Præsymptomatisk (IPS)	5	1,25	1	2	2	Litteratur se referenceliste i bilag 5
Symptomatisk (I)	4	7	5	7	9	Litteratur se referenceliste i bilag 5
Asymptomatisk (A)	4	7	5	7	9	Litteratur se referenceliste i bilag 5

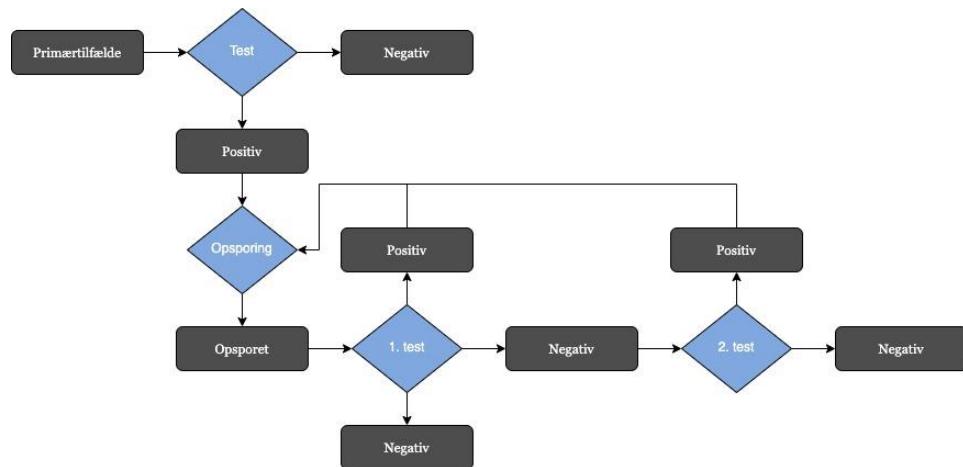

Hospitaliseret (H) Under 60 år	2	3	2	3	5	Linelisten SSI
Hospitaliseret (H) 60 år og der- over	2	5	3	5	7	Linelisten SSI
Ventetider						
timeSymp- ToOrderTest	5	1	1	1	1	Antagelser - af- venter STPS data
timeOrderTo- Test	2	2	1	2	3	Antagelser - af- venter STPS data
timeTestToRe- sult	6	1,5	2	2	2	Ventetider fra samfundssporet
traceDelay	5	1	1	2	3	Antagelser – af- venter STPS data

Sandsynligheden for, at en modtagelig agent bliver inficeret af en infektiøs agent og overgår til at være eksponeret i et givent netværk stiger med antallet af infektiøse agenter i netværket, de infektiøse agenter i netværkets smitsomhed, samt antallet af kontakter som både de modtagelige og infektiøse agenter har i netværket. Raten hvormed en modtagelig agent bliver inficeret er summen af smitterater fra de enkelte netværk, som agenten deltager i. Test og opsporing er indført i modellen ved følgende regler:

- Når en agent får symptomer, er der en sandsynlighed ($pTestGivenSymptoms = 80\%$) for, at de bestiller en test efter en gammafordelt ventetid (timeSympToOrderTest). Hvis der er bestilt en test, vil personen reducere sine kontakter til 50% (undtagen i husholdninger, hvor kontakter reduceres til 70%).
- Der er en gammafordelt ventetid fra testen bestilles, til testen udføres (timeOrderToTest).
- Der er en gammafordelt ventetid fra testen udføres, til der kommer svar (timeTestToResult).
- Hvis der kommer positivt svar, vil agenten isolere sig yderligere; kontakter reduceres til 10% (husholdning: 50%). Derudover påbegyndes opsporing af netværk under følgende regler:
 - I skoleklasser, ungdomsskoleklasser, institutioner og i husholdninger opspores alle personer (i husholdninger foregår det dobbelt så hurtigt som i de øvrige netværk).
 - På kontorer (arbejdspladser) og i omgangskredse opspores et antal nære kontakter givet ved fordeling af kontakter under 1m i data fra HOPE projektet.
 - Personer, som tidligere er testet positiv, får ikke tildelt yderligere test.
 - Der opspores med en gammafordelt forsinkelse (traceDelay) fra den positive test.
 - Ved opsporing efter en person testes positiv tildeles de opsporedes personer testtider relativt til 48 timer før den positive fik symptomer - eller blev testet i et asymptomatisk tilfælde. Hvis muligt, gives test på dag 4 og dag 6, ellers dag 5 og 7, og ellers én test hurtigt muligt.
 - Personer, som er i et igangværende opsporingsforløb, får kun tildelt test, hvis de venter på mindre end to testsvar.
 - Den opsporedes person har samme ventetider på testsvar, som symptomatiske personer.

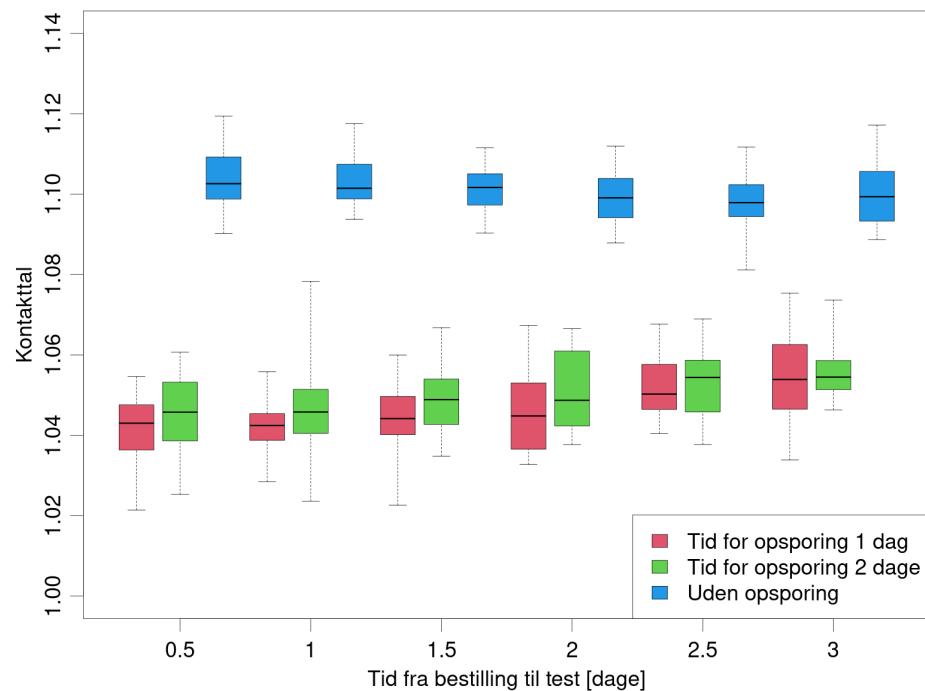

- Mens der ventes på test og testsvar, isoleres den opspored person på samme måde som en symptomatisk, der venter på svar.
- Hvis en opsporet person får negativt svar på den første test, vil der være en sandsynlighed for ($pNoShow2ndTest = 40\%$) at de ikke tager test nummer 2.
- Efter et negativt svar på test nummer 1, vil isolationen brydes. Hvis der fås et positivt svar, inden test nummer 2 er taget, annulleres test nummer 2, og personens egne netværk opspores.
- For alle tests – om det er en opsporet person eller ej – antages der en sandsynlighed på 20% for en falsk negativ test (Kucirka et al., 2020).

Figur 7. Diagram, der viser test og opsporing i den agentbaserede model fra DTU.

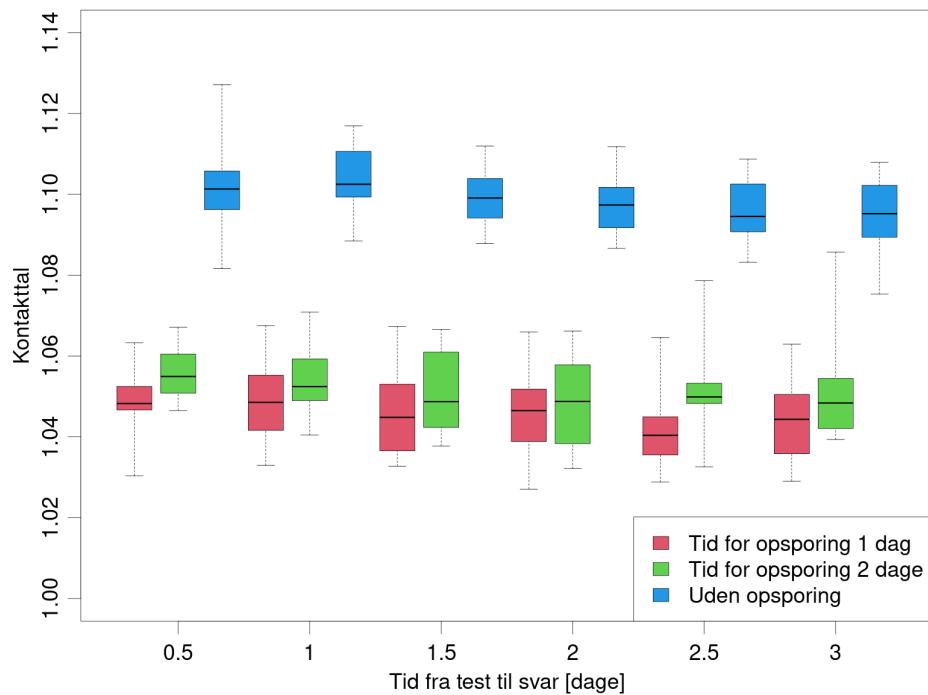

Yderligere resultater

Figur 8. Kontakttallets afhængighed af ventetiden på at få taget en test hos primærtilfældet, samt betydningen af hvor lang tid der går før nære kontakter opspores og går i tilsvarende isolation. For hver parameterværdi er der foretaget 40 simulationer og boxplottet viser median, de indre kvartiler samt minimum og maksimum af disse.

Af figur 8 fremgår det, at der ikke er nævneværdig forskel på reduktionen i kontakttallet, hvorvidt man reducerer ventetiden til at primærtilfældet testes, i forhold til at reducere ventetiden til opsporing af nære kontakter.

Figur 9. Kontakttallets afhængighed af tiden fra der testes til at der foreligger et testsvar, samt betydningen af hvor lang tid der går indtil nære kontakter opspores og går i tilsvarende isolations. For hver parameterværdi er der foretaget 40 simulationer og boxplottet viser median, de indre kvartiler samt minimum og maksimum af disse.

Af figur 9 fremgår det, at der ikke er nævneværdig forskel på reduktionen i kontakttallet, hvorvidt man reducerer ventetiden fra at primærtifældet og opspored kontakter testes til der foreligger et testsvar, i forhold til at reducere ventetiden til opsporing af nære kontakter. En årsag kan være, at ventetiden til testsvar gør, at en masse opspored og modtagelige kontakter er isoleret i længere tid og derfor ikke bliver smittet. Det er ikke undersøgt om dette kun ses når kontakttallet er nær 1.

Bilag 3. Regneeksempel

Følgende er et illustrativt regneeksempel på den agentbaserede model fra Niels Bohr Institutet beskrevet i bilag 1. Udregningerne er baseret på modellens underliggende antigelser, nemlig at perioden for eksposition ($E(T_E)$), hvor den latente fase er en gammafordeling med middelværdi på 4.7 dage, og perioden for den smitsomme fase er en gammafordeling med middelværdi på 7 dage, samt en antagelse om, at 40% af cases findes uden kontaktopsporing. Det antages, at for de COVID-19 tilfælde der findes uafhængigt af kontaktopsporningen, er de smittet uniformt fordelt i den smitsomme periode (I). Vi udregner nu tiden man er asymptomatisk men smitsom ved at trække tal fra fordelingen af tider for hele perioden, man er smitsom og tester en andel p , på et uniformt tilfældigt tidspunkt. Det giver en fordeling og en gennemsnitlig eksponeringstid (se figur 10A).

Vi kigger nu på et sekundært tilfælde, der blev smittet på et uniformt tilfældigt tidspunkt i den smitsomme periode for primærtildældet. Denne person kan enten findes tilfældigt, eller ved at primærtildældet testes, og at sekundærttilfældet opspores efter en tidsperiode (d for delay). Denne ventetid, er tiden fra at primærtildældet testes til at sekundærttilfældet kontaktes, og afspejler således både ventetid til test samt ventetid til opsporing. Ingen antages det, at sekundærtildældet går i isolation øjeblikkeligt. Ved igen at trække tal tilfældigt fra de relevante fordelinger fås en eksponeringsperiode, hvori sekundærttilfældet måske opspores, forhåbentligt inden smitten er ført videre.

Resultat

I figur 10B vises det gennemsnitlige antal dage en kontakt er eksponeret for smitte, som en funktion af den samlede ventetid til test og opsporing. Herudfra estimeres effekten af kontaktopsporing på det effektive kontakttal, R_t . Det antages, at en given andel (f_c) af alle smittetilfælde, findes via kontaktopsporing, og derved reduceres smitten, idet eksponeringsperioden for opspored kontakter reduceres. Herved fås et simpelt estimat af effekten af kontaktopsporing på kontakttallet R_t . Dette vises i figur 10C. Farverne på graferne viser, hvor stor en andel af smitten der kan reduceres, såfremt eksponeringsperioden reduceres, som følge af kontaktopsporing. Hvis det f.eks. antages, at der er 2000 nye smittede med COVID-19 per dag (ca. 1000 fundne smittede + et mørketal), så svarer 0.05 grafen (orange) til at 100 smittede bliver fundet gennem kontaktopsporing dagligt.

En væsentlig begrænsning er, at disse udregninger ikke medtager effekten af, at flere COVID-19 tilfælde bliver fundet pga. kontaktopsporing, men er udelukkende baseret på effekten ved at forlorte eksponeringsperioden for kontakter.

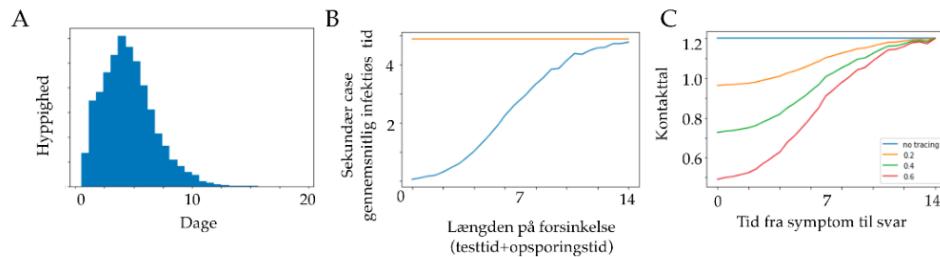

I modellen indgår 4 mulige eksponeringsperioder. 1: Kontakter opspores ikke, hvorved eksponeringsperioden ikke afkortes (blå graf), 2: 20% af kontakter opspores (gul graf), 3: 40% af kontakter opspores (grøn graf) og 4: hvis 80% af kontakter opspores (rød graf).

Af regneeksemplet fremgår det, at givet antigelserne i eksemplet vil kontakttallet kunne reduceres med ca. 50%, såfremt man opsporer 50% af alle kontakter inden for ca. 3 dage.

Bemærk at alle kurverne i figur 10C er meget flade i intervallet mellem dag 0 og 3. Dette betyder, at der kun opnås en lille gevinst ved at afkorte den samlede ventetid fra symptomer til der foreligger et testsvar inden for denne periode, men at der til gengæld er en stor gevinst ved at øge andelen af opspored kontakter.

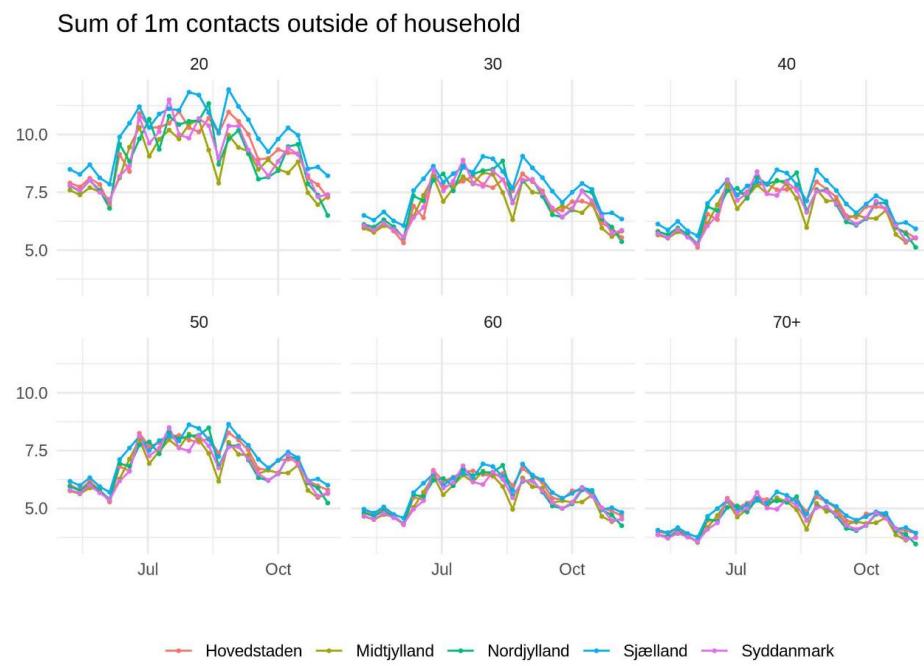

Det skal i øvrigt bemærkes, at det i eksemplet antages, at opspored kontakter går i isolations, indtil de får svar på deres test.

Figur 10:A) Fordeling af eksponeringstiden, gennemsnit = 4.9 dage. B) Gennemsnitlig eksponeringstid for sekundære tilfælde (blå), som funktion af den samlede ventetid til test og opsporing. Den orange graf viser gennemsnittet i ventetiden til test og opsporing for primærtilfældet som reference. C) Det effektive kontakttal R_t efter kontaktopsporing som funktion af ventetiden fra symptomer til testsvar hvor udgangspunktet er et kontakttal på 1.2, inden der iværksættes opsporing. Farverne indikerer hvor stor en andel af kontakter der opspores, hvorved eksponeringstiden reduceres.

Bilag 4. Udvikling i antal kontakter fra HOPE projektet

Figur 11. Kilde: Hope-projektet (12.11.2020). Estimating Local Protective Behavior in Denmark with dynamic MRP. https://github.com/mariefly/HOPE/raw/master/HOPE_report_2020-11-12.pdf

Bilag 5. Beskrivelse af parametre brugt i rapporten

Modellerne i rapporten bygger på en række parametre. Estimaterne, som parametre er baseret på er udvalgt af den relevante institution, der har udarbejdet modellerne. Begrundelsen for valg af estimaterne er beskrevet nærmere i dette bilag.

Overordnet set er parametre om sygdomsforløb primært baseret på international litteratur på emnet, men også på data fra den danske befolkning. Estimater over befolkningens adfærd i forbindelse med covid-19 bygger på en række danske undersøgelser fra i år, samt på data over danskernes rejsemønstre.

Estimater for latensperiode, inkubationsperiode og infektios periode fra litteraturen:

Særligt relevant for simuleringerne over effekten af kontaktopsporing er estimaterne bag sygdomsforløbet, herunder hvor lang tid der går fra eksponering til, at vedkommende kan smitte, og derefter til, at vedkommende vises symptomer. Estimaterne i modellen er blandt andet baseret på andre forskeres data, som er offentliggjort i international litteratur om covid-19.

For at finde de bedste estimat på *latensperioden* har modelgruppen trianguleret distributioner fra nedenstående kilder. Estimatet er 3,6 dage med et interval på mellem 3-5 dage.

- Read et al. (2020). Novel coronavirus 2019-nCoV: Early estimation of epidemiological parameters and epidemic predictions. *Preprint*.

- Milne and Xie (2020). The Effectiveness of Social Distancing in Mitigating COVID-19 Spread: a modelling analysis. *Preprint*.

For at finde det bedste estimat af *inkubationsperioden*, har Ekspertgruppen gennemgået nedenstående litteratur. Estimatet er 5 dage med et interval på mellem 3-7 dage.

- Milne and Xie (2020). The Effectiveness of Social Distancing in Mitigating COVID-19 Spread: a modelling analysis. *Preprint*.

For estimatet af *den infektiøse periode*, hvor det bedste estimat er 5 dage, mens det bedste interval er mellem 3-7 dage, har Ekspertgruppen gennemgået følgende artikler:

- Read et al. (2020). Novel coronavirus 2019-nCoV: Early estimation of epidemiological parameters and epidemic predictions. *Preprint*.
- Prem et al (2020). The effect of control strategies that reduce social mixing on outcomes of the COVID-19 epidemic in Wuhan, China. *Centre for the Mathematical Modelling of Infectious Diseases COVID-19 Working and Jit, Mark and Klepac, Petra, The Effect of Control Strategies that Reduce Social Mixing on Outcomes of the COVID-19 Epidemic in Wuhan, China*.
- Milne and Xie (2020). The Effectiveness of Social Distancing in Mitigating COVID-19 Spread: a modelling analysis. *Preprint*.

HOPE rapporter og data:

En del af estimatorne i modellerne om befolkningens adfærd, herunder kontaktmønstre, bygger på både data og rapporter for Hope-projektet (<https://hope-project.dk/#/>).

HOPE-projektet udsender løbende spørgeskemaer til tilfældigt udvalgte personer i Danmark vedrørende både deres tillid til myndighederne, og til deres adfærdsmønstre, herunder hvor mange de ses med i forskellige kontaktkategorier, hvor meget afstand de holder fra andre mennesker etc. Denne information samles i rapporter, der løbende offentliggøres.

Udover HOPE-rapporten, der henvises til i Bilag 4 (https://github.com/marie-flu/HOPE/raw/master/HOPE_report_2020-11-12.pdf), oversender HOPE-projektet løbende anonymiserede data om befolkningens adfærd under covid-19 til Ekspertgruppen, der anvender det i deres modeller. Ekspertgruppen har også adgang til HOPE-projektets rapporter, der sammenskriver data.

Trafik data:

Antagelser om befolkningens adfærd bygges ligeledes på trafikdata, hvorudfra man kan bestemme danskernes rejsemønstre. Efter aftale med Trafik-, Bygge- og Boligstyrelsen får Ekspertgruppen løbende adgang anonymiserede data over danskernes bevægelse rundt i landet. Data er bl.a. brugt til at bestemme den typiske afstand mellem kontakter og afstanden mellem afstands-uafhængige kontakter. Data bygger på 5 forskellige kilder:

- Overblik over rejsende, der bruger rejsekort, som kommer fra Rejsekort og Rejseplanen A/S
- Overblik over biltrafik på Øresunds- og Storebæltsbroen fra Sund og Bælt A/S

- Overblik over flytrafik (antal passagerer) til og fra Københavns Lufthavn og Billund Lufthavn
- Overblik over biltrafikken på Statsvejsnettet og cykeltrafikken (samlet ud fra tællestandere) leveret af Vejdirektoratet.
- Overblik og færgetrafik på 5 rederier, der dækker over 17 færgeruter. Data er leveret af Danske Rederier.

Estimater for ventetider til test

Estimater for ventetider til test og svar på test er taget fra TCDKs hjemmeside (<https://tcdk.ssi.dk/vente-og-svartider>).

Data fra SSIs Linelisten

Linelisten på SSI indeholder informationer om de covid-19 podninger, der tages en given dag. Data fra Linelisten er bl.a. brugt til at modellere risikoen for at blive hospitaliseret i løbet af et covid-19-forløb for personer over og under 60 år.

Spørgeskemaundersøgelse blandt covid-19 syge lavet af SSI i foråret:

I foråret 2020 foretog SSI en telefonisk spørgeskemaundersøgelse blandt en række personer, der fik konstateret covid-19. Spørgsmålene undersøgte deltagernes sygdomsforløb, herunder symptomer, hvorvidt nære kontakter i husstanden var smittet og lignende.

Data fra spørgeskemaundersøgelsen blev i modellerne brugt til at estimere tiden fra symptomdebut til tests i dage.

Den nationale prævalensundersøgelse for covid-19:

SSI iværksatte i maj en undersøgelse af, hvor udbredt covid-19 var blandt danskerne. Undersøgelsen bestemmer seroprævalencen blandt et repræsentativt udsnit af danskerne fra maj og til i dag. Informationen fra prævalensundersøgelsen har været anvendt i modellerne til at estimere sandsynligheden for at få symptomer og blive testet.

Bilag 6. Medlemmer af ekspertgruppen

Ekspertgruppen ledes af læge Camilla Holten Møller og overlæge Robert Leo Skov, Infektionsberedskabet, Statens Serum Institut.

B *SSI Notat*

The following pages contain the report from Statens Serum Institut, the Danish CDC: *Ekspertgruppen for matematiske modelleringscenarier for udviklingen i den engelske virusvariant af SARS-COV-2 (cluster B.1.1.7)* (Statens Serum Institut, 2021).

The report is from January 2 2021 and is a summary of the estimated spread of the “alpha” variant of COVID-19 (B.1.1.7) in Denmark. The report is in Danish and is based on two models, one from DTU and our agent based model from NBI.

d. 2. januar 2021

Notatet er opdateret d. 22. januar 2021 med en præcisering af formuleringer vedrørende udviklingen i forholdet mellem Cluster B.1.1.7 og øvrige virusvarianter.

Scenarier for udviklingen i den engelske virusvariant af SARS-COV-2 (cluster B.1.1.7)

Ekspertgruppen for matematisk modellering, der ledes fra SSI, bringer i dette notat en række estimerer for den forventede udbredelse af cluster B.1.1.7 i den kommende periode, dels ved logistisk regression af udviklingen i forekomsten af varianten, og dels ud fra simuleringer af spredningen af varianten i en agentbaseret model.

Sammenfatning

- Den observerede udvikling i forekomsten af cluster B.1.1.7 i Danmark, svarer til en ugentlig vækstrate for forholdet mellem cluster B.1.1.7 og de øvrige virusvarianter på 72% (95% CI: [37, 115] %).
- Med udgangspunkt i den aktuelle situation hvor 2,3% af virusvarianterne i den rutinemæssige helgenomsekivering tilhører cluster B.1.1.7, estimeres det, at varianten vil udgøre halvdelen af de cirkulerende virusstammer i Danmark om 40-50 dage såfremt ovennævnte stigning fortsætter.
- Det nuværende niveau af restriktioner forventes ikke at være tilstrækkeligt til at få kontakttallet for cluster B.1.1.7 under 1. Derfor vil denne vokse eksponentielt upåagtet at det samlede kontakttal (for alle virusvarianter) kan være under 1 indtil cluster B.1.1.7 overtager om omkring en måned.
- Forekomsten af cluster B.1.1.7 er højest i Region Nordjylland, og udviklingen i forekomsten er ca. fire uger foran Region Hovedstaden.
- Det er på baggrund af engelske data estimeret at kontakttallet er ca. 1,5 gange højere for den nye virusvariant i forhold til andre virusvarianter.
- Den reduktion i smittetal og indlæggelser, der kan opnås i den kommende måned vil give et lavere udgangspunkt for den forøgede smitte og stigende kontakttal, som vi må forvente.

Disse beregninger er behæftet med usikkerheder af forskellige grunde. I perioden op til jul var der stor efterspørgsel på tryghedstest, og i samme periode er der udført et stigende antal antigen test. Derimod så vi i juledagene, at kun ganske få har ladet sig teste. Disse ændringer i testdynamikker gør det svært at følge udviklingen i covid-19, idet de vanlige indikatorer såsom incidenser, positivprocenter og kontakttallet påvirkes af den ændrede fordeling af covid-19-positive blandt de testede. Et lignende mønster forventes i dagene op til og efter nytår. Desuden har vi endnu ikke set effekten af de sidst indførte tiltag, herunder lukning af detailhandlen og liberale erhverv. Samlet set giver dette usikkerhed omkring det aktuelle kontakttal. Analysen er baseret på 76 isolater med cluster B.1.1.7 fordelt på de fem regioner. Den lille stikprøve giver relativt store statistiske usikkerheder. Der vil derfor være behov for at løbende at opdatere estimaterne og lave nye analyser.

Logistisk regression for spredningen af cluster B.1.1.7

Som det fremgår af nedenstående tabel, er der stor forskel på, hvornår man har fundet cluster B.1.1.7 i de enkelte regioner.

Tabel 1. Forekomst af cluster B.1.1.7 i de fem regioner baseret på helgenomsekventering af stikprøver af SARS-CoV-2 positive isolater.

Uge	Hovedstaden		Midtjylland		Nordjylland		Sjælland		Syddanmark	
	B.1.1.7	Total	B.1.1.7	Total	B.1.1.7	Total	B.1.1.7	Total	B.1.1.7	Total
45	0	656	0	283	0	238	0	181	0	200
46	4	420	0	327	0	305	0	132	0	168
47	0	588	0	297	0	240	0	143	0	241
48	3	679	0	291	0	169	0	165	0	195
49	0	825	0	332	3	64	0	246	0	208
50	2	892	0	360	7	92	0	214	1	431
51	3	753	0	524	9	254	3	310	4	354
52	8	774	5	221	12	169	10	193	1	225

Ud fra udbredelsen af cluster B.1.1.7 i Danmark samt andelen af nye isolater i overvågningen som er relateret til clusteret, anvendes logistisk regression til at estimere den forventede udbredelse af cluster B.1.1.7. Da fokus er på spredningen af virusvarianten, og ikke på introduktioner af denne, er det kun regioner, hvor der er detekteret isolater tilhørende cluster B.1.1.7 i mindst fire uger – dvs. Region Hovedstaden og Region Nordjylland, der er medtaget i denne første analyse.

Der er lavet logistisk regression med uge og region som forklarende variable. Der er også testet en interaktion, men den er ikke signifikant.

Tabel 2. Estimater for logistisk regression af andelen af cluster B.1.1.7. Referencen repræsenterer Region Hovedstaden.

	Estimate	Std. Error	z value	Pr(> z)
(Intercept)	-32.812	5.679	-5.778	0.000
Uge	0.540	0.112	4.844	0.000
Region Nordjylland	2.221	0.311	7.133	0.000

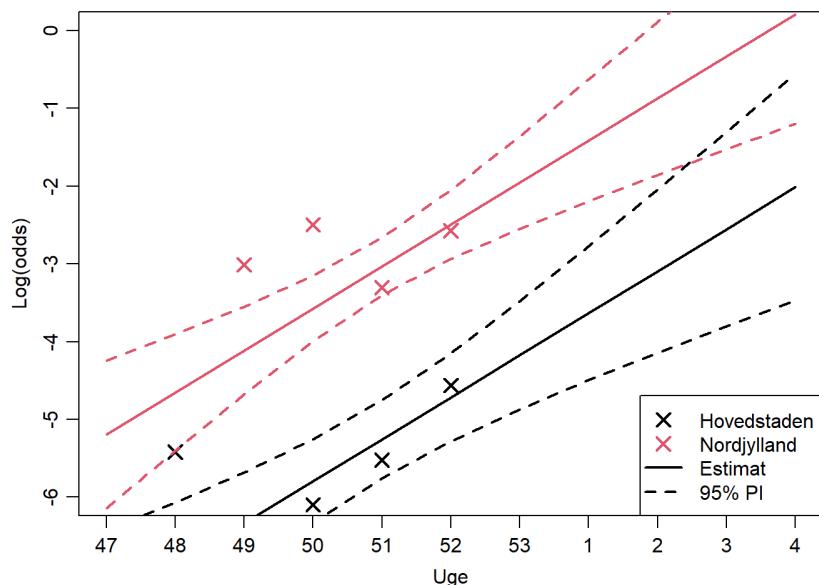

Det ses, at log(odds) for at detektere cluster B.1.1.7 er 2.2 højere i Region Nordjylland end i Region Hovedstaden. Det svarer til odds på 9.2. Det mest interessante er den tidslige udvikling, hvoraf det ses at log(odds) øges med 0.54 for hver uge. Dette svarer til at cluster B.1.1.7 har en ugentlig vækstrate i odds (forholdet mellem antal cluster B.1.1.7 og øvrige virusvarianter) på 72% (95% CI: [37, 115] %), hvilket med den nuværende lave andel af cluster B.1.1.7 svarer til den samme stigning i andelen af cluster B.1.1.7 blandt alle positive prøver. Usikkerheden på estimatet er endnu ganske stort og estimatet er følsomt over for hvilke uger der medtages. Uanset usikkerheder, svarer det fundne estimat til de der er rapporteret fra England for denne virusvariant og det tyder på, at cluster B.1.1.7 har samme forøgede transmissionsrate i Danmark som i England.

Det ses, at log(odds) for at detektere cluster B.1.1.7 er 2.2 højere i Region Nordjylland end i Region Hovedstaden. Det svarer til odds på 9,2, dvs. at sandsynligheden for at detektere cluster B.1.1.7 her er 9,2 gange højere. Det svarer også til at Region Nordjylland er fire uger foran Region Hovedstaden i andelen af cluster B.1.1.7

Det forventes, at usikkerhederne vil blive reduceret væsentligt når der er data for 1-2 uger mere. Men givet at B.1.1.7 er så meget mere smitsom end hidtidige varianter vil det kræve længerevarende restriktioner at sænke smittetallet.

De seneste estimerater af kontakttallet er lige under 1,0. Dette er dog påvirket af den ændrede testaktivitet og adfærd hen over jul og nytår, og vi har endnu ikke et overblik over konsekvenserne af sammenkomster i forbindelse med jul og nytår. Endvidere har vi endnu ikke set effekten af nedlukningen af de liberale erhverv og detailhandlen omkring jul. Derfor er det forventningen, at en fastholdelse af de nuværende restriktioner vil give et fald i kontakttallet, hvis man kigger på de virusvarianter som vi har set før introduktionen af cluster B.1.1.7. I England har man estimeret, at deres reference kontakttal var 0,8 for andre virusvarianter og 1,2 for cluster B.1.1.7. Det observerede kontakttal er et vægtet gennemsnit af virusvarianterne i populationen.

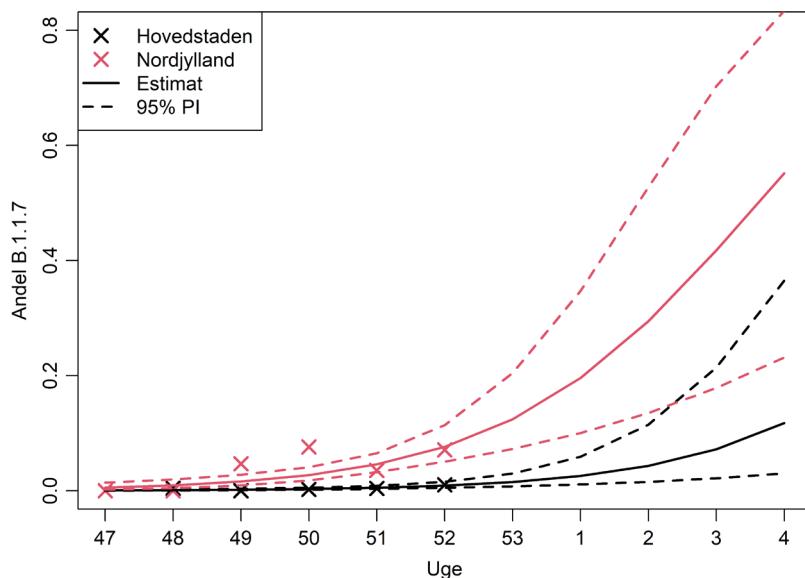

Figur 1 viser en fremskrivning af log(odds) for B.1.1.7 mod andre virusvarianter baseret på ovenstående logistiske regression. Estimatet er, at cluster B.1.1.7 allerede i uge 4 vil udgøre halvdelen af alle positive test i Region Nordjylland. Dette er dog behæftet med stor usikkerhed på baggrund af de nuværende data.

Figur 1. Log(odds) for at detektere cluster B.1.1.7 i hhv. Region Hovedstaden og Region Nordjylland

Ved sammenligning med England er vi nu, hvor de var i starten af november, hvor South East havde log(odds) på -2 svarende til Nordjylland og både London og East of England havde log(odds) omkring -4 svarende til Hovedstaden¹

Figur 2 viser den samme fremskrivning som i figur 1. Blot er der transformeret tilbage til andelen af positive test, som tilhører cluster B.1.1.7.

¹ 2020_12_23_Transmissibility_and_severity_of_VOC_202012_01_in_England.pdf
(cmmid.github.io)

Figur 2. Udviklingen i forekomsten af cluster B.1.1.7 i de kommende uger. Fremskrivningen viser, at halvdelen af isolaterne i Region Nordjylland vil være cluster B.1.1.7 omkring uge 4.

Det skal bemærkes, at udviklingen i Hovedstaden er ca. 4 uger efter udviklingen i Nordjylland. Det er endnu for tidligt at udtales sig om niveauet i de andre tre regioner, men særlig Region Sjælland synes at have oplevet en hurtig stigning, om end det er baseret på meget lidt data. De næste par uger vil forbedre estimatet af niveauet i alle regioner.

Hen over julen har der været et nyt toppunkt i antal indlagte og der er endnu kun set små fald. Det er først i uge 1, at vi kan forvente at se eventuelle indlæggelser som følge af smitte i julen. Alt andet lige må dette forventes at give en yderligere kortvarig pukkel i antal nye indlæggelser.

På nuværende tidspunkt er prognosen, at vi har omkring en måned før det samlede kontakttal for alle virusvarianter hurtigt vil stige på grund af øget udbredelse af cluster B.1.1.7. Hvis restriktionerne skærpes i den kommende tid, vil det give en reduktion i smittetal og indlæggelser og dermed et lavere udgangspunkt for den forøgede smitte og stigende kontakttal, som vi må forvente.

Et første estimat af kontakttallet for cluster B.1.1.7 for perioden uge 47 til 52 og baseret på observationer fra Region Hovedstaden og Region Nordjylland er 1.5 (95% CI [1,2 ; 1,7]) - dette er estimeret vha. Poisson regression med offset lig med $0.7 * \log(\text{antal sekventerede})$. Det gennemsnitlige kontakttal (baseret på SSIs publicerede kontakttal 2020-12-29) for perioden er 1,1. Da kontakttallet for cluster B.1.1.7 er så meget højere må det selv med de nuværende restriktioner forventes, at det vedbliver med at være over 1 og dermed forventes cluster B.1.1.7 at vokse eksponentielt, hvis det nuværende niveau af restriktioner fastholdes.

Simulering af spredningen af cluster B.1.1.7 i en agentbaseret model

Agentbaserede modeller

Spredningen af cluster B.1.1.7 er simuleret i en agentbaseret model, som er udviklet af Niels Bohr Institutet, Københavns Universitet (NBI). En agentbaseret model simulerer et antal agenter (individer i en population) og deres interaktioner med andre agenter, svarende til de interaktioner som en befolkning normalt viser. Hver agent repræsenterer således en person, som er knyttet til en lokation i Danmark, svarende til deres bopæl. Agenterne indgår i flere forskellige netværk, f.eks. husstand, job og skole hvor de har kontakt til andre personer. Derudover har de kontakt til tilfældige personer i samfundet i den tid, hvor personen ikke er hjemme, på job eller i skole. Hvis en agent bliver smittet med SARS-CoV-2, er forløbet for den enkelte agent beskrevet således, at agenten først er eksponeret (E) og derefter infektiøs (I), hvorefter agenten ikke længere er smitsom og betragtes som rask (R). De gennemsnitlige tider i hvert sygdomsstadiet kan findes i bilag 1. Hver kontakt, som en agent eksponeres for, tildeles en sandsynlighed for at blive smittet af en anden agent, såfremt denne er smitsom. For en detaljeret beskrivelse af den agentbaserede model, herunder de inkluderede parametre, henvises til bilag 1.

Forbehold

Mens en agentbaseret model kan medtage mere detaljerede dynamikker i en epidemi, så kræver en præcis simulation input fra data, som ofte ikke er tilgængelige eller forefindes, fx hvem en person mødes med i løbet af en dag. Derfor kan en sådan model have unøjagtigheder eller bygge på antagelser, som ikke er retvisende. Det er ikke muligt at kvantificere den nøjagtige størrelse eller effekt af disse potentielle fejlkilder. Da datagrundlaget for disse simuleringer er sparsomt, fordi vi endnu har få datapunkter for cluster B.1.1.7, vil resultatet være behæftet med væsentlig usikkerhed.

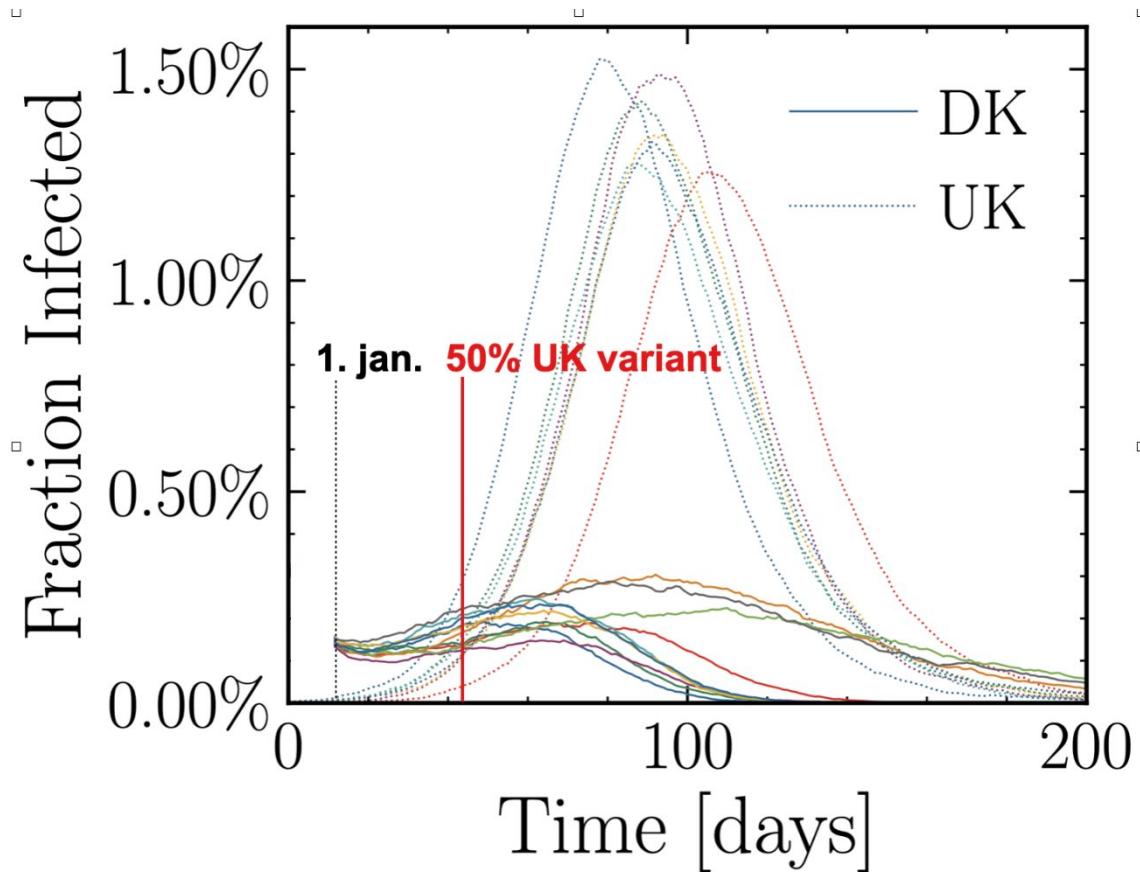

Resultater

I det følgende er udviklingen simuleret i en model, hvor udgangspunktet er 1/10 af Danmarks befolkning, og hvor cluster B.1.1.7 fra starten udgør omkring 5% af de cirkulerende virusvarianter. Epidemien simuleres ud fra et kontakttal på omkring 1,0, samt en antagelse om, at cluster B.1.1.7 smitter 50% mere, som rapporteret fra England²

Figur 3 viser, hvordan en epidemi vil udvikle sig i tid, forudsat at det simulerede scenarie ikke ændres. Der opdeles i hhv. de nuværende virusvarianter (DK, fulde linjer) og det engelske cluster B.1.1.7 (UK, stiplede linjer). Simulationen er gentaget flere gange (forskellige farver) for at se, hvor store variationer der forekommer. Som det kan ses, så udfases DK-versionen af smitten, mens UK-versionen B.1.1.7 giver ophav til en eksponentiel vækst, idet kontakttallet for denne er væsentligt over 1.

Af figuren fremgår det, at cluster B.1.1.7 ca. 35-40 dage fra simulationens start ("1. jan.") udgør omkring 50% af de cirkulerende virusvarianter. Da simulationen er startet med en større andel UK-varianter (5%) end det aktuelle landsgennemsnit (2.3%), så bliver estimatet 40-50 dage til at halvdelen af de sekventerede varianter tilhører cluster B.1.1.7. I de viste simulationer er de første smittet med cluster B.1.1.7 varianten placeret i Hovedstadsområdet. I andre scenarier, hvor cluster B.1.1.7 varianten i starten udvikler sig i et tyndere befolket område tager udviklingen lidt længere tid, op til 60 dage.

Figur 3. Den forventede udvikling i cluster B.1.1.7 sammenholdt med udviklingen i øvrige virusvarianter, simuleret i en agentbaseret model. Ud fra simulationerne estimeres det, at B.1.1.7 varianten vil være dominerende efter 40-50 dage.

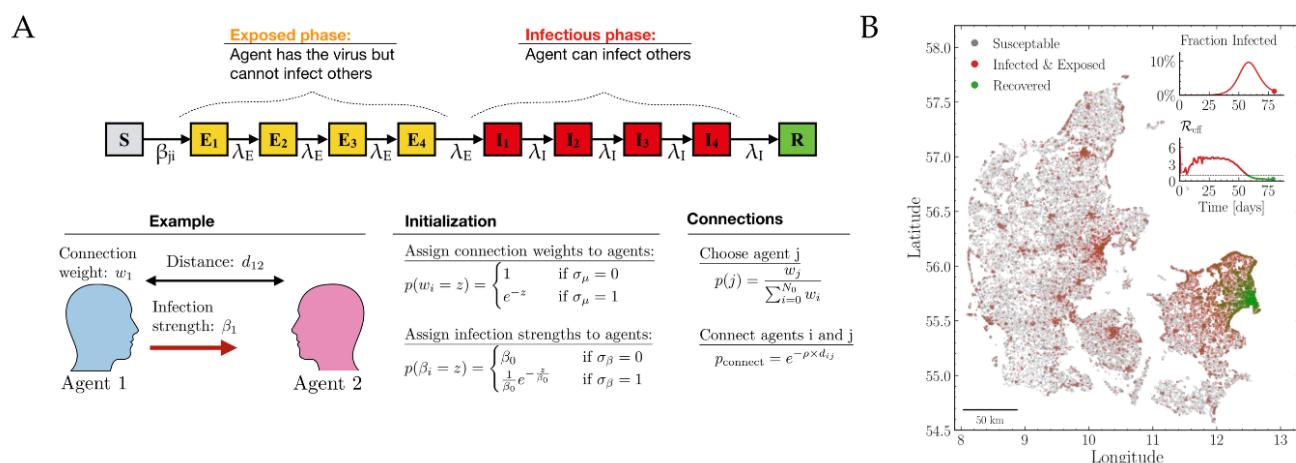

Bilag 1. Beskrivelse af den agentbaserede model

Den nedenstående modelbeskrivelse er et uddrag fra ekspertrapporten "effekten af kontaktopsporing" der er publiceret d. 16. december 2020

Bidrag og udvikling: Christian Michelsen, Emil Martiny, Tariq Halasa, Mogens H. Jensen, Troels C. Petersen og Mathias L. Heltberg

Den agentbaserede model baseres på agenter, dvs. individer hvis karakteristika er tildelt ud fra statistiske fordelinger i befolkningen. Dette er f.eks. en aldersfordeling og en fordeling over pendlerafstande. Modellen starter med at fordele Danmarks bopæle ud i landet baseret på det danske hussalg over de sidste 15 år. Herefter placeres agenter i hver husstand baseret på deres alder og geografiske placering.

Figur 5: A) Skematisk oversigt over hvordan interaktionsnetværket i modellen ser ud. B) Eksempel på simulation af smittespredning i Danmark i modellen, gennem et simuleret tilfælde af flokimmunitet i København.

Et afgørende element i modellen er opbygningen af alle personers interaktionsnetværk. Dette genereres ved, at hver agent har et netværk, de interagerer med. Dette opdeles i tre dele: 1) kontakter i hjemmet, 2) kontakter på arbejdet, 3) kontakter i kategorien andre kontakter. Der er ikke nogen geografisk afhængighed af antallet af kontakter på arbejdet, men i den kategori der kaldes "andre", vil der generelt være flere kontakter for dem der bor i tæt befolkede områder i forhold til dem der bor på landet. Måden hvorpå netværket dannes er vist i Figur 5A.

Ud fra data fra HOPE-projektet har vi estimeret, hvor mange personer hver agent vil interagere med, og i denne model vil alle agenter have mellem 3 og 15 daglige kontakter.

Når modellen simuleres vil alle inficerede agenter gennemgå et forløb, hvor de er i en latent periode, hvor de ikke smitter, hvorefter de vil rykke over i en infektiøs periode, hvor de kan smitte agenter i deres netværk. Denne model simuleres ud fra det der kaldes Gillespie algoritmen, således at netværket opdateres instantan for alle smittebegivenheder. En samling af de væsentligste parametre er vist herunder (Tabel 2).

Tabel 2: Parametre i den agentbaserede model

Parameter	Værdi interval for middelværdien	Reference
Antal kontakter per dag	3-15	HOPE projektet
Latent tid (dage)	3-5	Litteratur se referenceliste i bilag 5
Infektiøs tid (dage)	4-8	Litteratur se referenceliste i bilag 5
Andel af kontakter i "andre" (%)	30-80	HOPE projektet
Typisk afstand mellem kontakter (km)	5-20	Trafik data
Andel afstandsufhængige kontakter (%)	3-5	Trafik data
Tid fra symptom til test (Dage)	0-2	Fordeling fra spørgeskemaundersøgelse i foråret 2020 (ikke offentliggjort)
Sandsynlighed for at få symptomer og blive testet (%)	20-60 %	Prævalensundersøgelsen
Sandsynlighed for at kontakte husstand (%)	100%	Antagelse
Sandsynlighed for at kontakte kollegaer (%)	40-80	Antagelse
Sandsynlighed for at kontakte andre (%)	0-75	Antagelse
